We have previously shown that different isolates of *Chlamydia pneumoniae* display heterogeneity in the in vitro stimulation of chemokines and adhesion molecules from infected human endothelial cells. In the present study, we examined the ability of different isolates of *C. pneumoniae* to promote transendothelial migration of neutrophils and monocytes. Human umbilical vein endothelial cells (HUVEC) were infected with low (<15)-, passage *C. pneumoniae* isolates A-03, PS-32, and BR-393 and high (>40)-passage isolates BAL-16, TW-183, and T-2634, and levels of neutrophil and monocyte transendothelial migration were determined following 24 h of infection. Compared to mock-infected controls, significant increases in neutrophil migration were observed in response to most *C. pneumoniae* isolates examined (*P < 0.001*). Levels of monocyte migration were significantly increased in response to TW-183 and T-2634 (*P < 0.001*). Serial passage (>40 times) of the three low-passage isolates in HEp-2 cell cultures prior to infection of HUVEC generally resulted in the promotion of higher levels of neutrophil and monocyte transendothelial migration. These findings were compatible with differences observed in the extent of interleukin-8 (IL-8) and monocyte chemotactic protein-1 (MCP-1) stimulation between low- and high-passage A-03, PS-32, and BR-393. As opposed to *C. pneumoniae*, infection with *C. trachomatis* L2 caused only a slight increase in neutrophil transendothelial migration, which correlated with the lack of measurable IL-8 levels by this species. However, significant levels of monocyte migration were induced in response to *C. trachomatis* L2 despite a lack of measurable MCP-1 stimulation. *C. trachomatis* serovars A and E also failed to induce IL-8 and MCP-1 production in HUVEC. Results from this study indicate that the passage history of *C. pneumoniae* may play a role in the divergence of stimulatory activities observed among isolates in human endothelial cells. In addition, the differences observed between this organism and *C. trachomatis* suggest that the upregulation of IL-8 and MCP-1 in endothelial cells may be unique to *C. pneumoniae*.

*Chlamydia pneumoniae* causes acute respiratory infections, including sinusitis, bronchitis, and pneumonia (6, 7). Infections with this organism may also become chronic following acute illness, despite appropriate antibiotic therapy (10). A role for *C. pneumoniae* in chronic inflammatory diseases has been suggested by data showing a propensity for patients with previous respiratory infection to develop asthmatic bronchitis (8, 9) and by the physical and serological evidence implicating an association of this organism with atherosclerosis (18, 19, 22, 24, 28, 32, 34). The recent isolation of *C. pneumoniae* from human carotid (15) and coronary (23, 29) atherosomas provides further support for an association of this bacterium with atherosclerosis. We have previously shown that the upregulation of IL-8 and MCP-1 in endothelial cells may provide a better understanding of the role of this organism in atherosclerosis. We have previously shown that infection of human endothelial cells with *C. pneumoniae* induces the production of IL-8 and MCP-1 and found heterogeneity in the extent of activation of these chemokines among different isolates (26). The present study investigated the capability of different *C. pneumoniae* isolates to stimulate the transendothelial migration of neutrophils and monocytes in an in vitro model of the human vascular wall.

**MATERIALS AND METHODS**

*Chlamydia isolates.* *C. pneumoniae* A-03 (ATCC VR-1452) was isolated from an atheroma of a patient with coronary artery disease (29). *C. pneumoniae* PS-32 was isolated from a carotid atheroma (15) and was kindly supplied by J. Thomas Grayston, University of Washington, Seattle. Respiratory isolates BAL-16 and T-2634 were provided by Margaret Hammerschlag, State University of New York, Brooklyn. BR-393 was a recent respiratory isolate and a gift from Charlotte Gaydos, The Johns Hopkins University, Baltimore, Md. *C. pneumoniae* TW-183 was purchased from the Washington Research Foundation, Seattle. All isolates were propagated in HEp-2 cell cultures (ATCC CCL-23) as previously

**Supporting information:**

**Figure 1.** Bar graph illustrating neutrophil transendothelial migration following infection of HUVEC with different *C. pneumoniae* isolates. Bars represent mean ± SEM. 

**Figure 2.** Bar graph illustrating monocyte transendothelial migration following infection of HUVEC with different *C. pneumoniae* isolates. Bars represent mean ± SEM.
described (26). Low-passage (LP) A-03, PS-32, and BR-393 stock cultures had undergone <15 passages in HEP-2 cells, while the remaining isolates (high-passage [HP] stock cultures) had been passed >20 times before these experiments. The A-03, PS-32, and Chlamydia trachomatis L2/434 was a gift from James B. Mahoney, McMaster University Regional Virology and Chlamydiology Laboratory, Hamilton, Ontario, Canada. C. trachomatis A/HAR-13 and E/BOUR were kindly provided by Gerald Byrne, University of Wisconsin, Madison.

**Endothelial cell cultures.** Human umbilical vein endothelial cells (HUVEC; ATCC 1730-CRL) were cultured in 75-cm² culture flasks and maintained in Ham’s F12K medium (Stigma, St. Louis, Mo.). Cell medium was supplemented with fetal bovine serum (1%), 2-mg/ml gentamicin, 1% penicillin-streptomycin-ampicillin (B [Fungizone] mix; BioWhittaker, Walkersville, Md.), 30 µg of endothelial cell growth supplement per ml, and 100 µg of heparin (Sigma) per ml. For leukocyte migration studies, HUVEC were seeded in 6.5-mm Transwell-Clear inserts (Corning Costar, Cambridge, Mass.) at a density of 4 × 10⁶ cells/well and allowed to reach confluency for 2 days before infection. The formation of confluent monolayers was verified by silver nitrate stain and microscopic examination under a 400× objective (35). Intercellular junction integrity of the endothelial monolayer was also assessed by measuring the permeability to bovine serum albumin as described elsewhere (13). For the IL-8 and MCP-1 experiments, HUVEC were seeded in gelatin-coated 24-well plates at a density of 2 × 10⁵ cells/well and allowed to adhere overnight prior to infection. The cell number and viability of HUVEC were not significantly diminished following the described incubation periods, as determined by direct counting of trypanized cells with a hemacytometer and by trypan blue dye exclusion, respectively.

**Infection protocol.** HUVEC monolayers in 6.5-mm transwells or 24-well plates were infected with each isolate of *C. pneumoniae* or *C. trachomatis* suspended in inoculation medium (Isco’s minimal essential medium supplemented with 10% fetal bovine serum, 2 mM L-glutamine, 1% [vol/vol] nonessential amino acids, 10 mM HEPES, 4 mg of glucose per ml [pH 7.5], 10 µg of gentamicin per ml, and 25 µg of vancomycin per ml). Cells grown in 6.5-mm transwells received 4 × 10⁴ inclusion-forming units (IFU) per well, while cells grown in 24-well plates were inoculated with 2 × 10⁵ IFU per well, resulting in a multiplicity of infection of 1:1 for each case. In addition to infection with viable chlamydiae, HUVEC were infected with organisms that had been previously inactivated by heat (90°C for 30 min) or UV light (12-h exposure to a model UVSL-25 Mineralight UV lamp at a distance of 2 cm). For the transendothelial migration experiments, infection was performed by incubation for 2 h at 37°C in 5% CO₂. Following incubation, the medium was aspirated, cell monolayers were washed with Hank’s balanced salt solution (HBSS), and fresh inoculum medium was added to the cultures. For the chemokine experiments, infection was performed by centrifugation as described previously (26). Since the *C. pneumoniae* inoculum may contain high numbers of nonviable *C. pneumoniae* cells, mock-infected controls were used to ensure that all observed increases in migration and chemokine production were due to viable *C. pneumoniae*. Infection with *C. pneumoniae* was confirmed by commercially available enzyme-linked immunosorbent assay (ELISA) kits (R&D Systems). The ELISAs were performed according to the manufacturer’s instructions.

**Data analysis.** Raw data of experimental groups from the transendothelial migration and chemokine assays were subjected to an unpaired analysis of variance with the Tukey-HSD multiple-comparison test. A *P* < 0.05 was used as the alpha value to determine statistical significance for all analyses.

## RESULTS

### Transendothelial migration of neutrophils and monocytes in response to infection with *C. pneumoniae*

We examined the abilities of different isolates of *C. pneumoniae* to stimulate the migration of neutrophils and monocytes across infected endothelial cells. HUVECs were infected with LP isolates A-03, PS-32, and BR-393 or HP isolates BAL-16, TW-183, and T-2634, and levels of migration were determined following 24 h of infection. As shown in Fig. 1, the extent of neutrophil and monocyte migration stimulated by *C. pneumoniae* infection was dependent on the isolate examined. Significant increases in neutrophil transendothelial migration were observed in response to most *C. pneumoniae* isolates compared to mock-infected controls. These increases were approximately threefold for A-03 LP and PS-32 LP, fourfold for BAL-16 and TW-183, and fivefold for T-2634 (*P* < 0.001) (Fig. 1A). Little increase was observed in response to BR-393 LP. Use of heat-inactivated *C. pneumoniae* caused a significant reduction in the stimulation of neutrophil transendothelial migration by most isolates compared to live organisms (*P* < 0.05). The response to UV-inactivated *C. pneumoniae* was decreased by an average of 50% for most isolates and not found to be statistically significant compared to viable bacteria for A-03-LP, BAL-16, and TW-183. As depicted in Fig. 1B, only isolates TW-183 and T-2634 stimulated significant levels of monocyte migration compared to mock-infected controls. This response was approximately fourfold higher than for the mock-infected controls (*P* < 0.001) and was significantly lower after heat and UV light inactivation (*P* < 0.05 compared to viable bacteria). The remaining four isolates (A-03 LP, PS-32 LP, BR-393 LP, and BAL-16) induced only a moderate increase in monocyte transendothelial migration above the level for mock-infected controls which was not statistically significant (*P* > 0.05).

### Effects of passage history on the stimulation of neutrophil and monocyte transendothelial migration by *C. pneumoniae*

To investigate whether the number of passages in HEP-2 cell cultures influenced the ability of *C. pneumoniae* to stimulate leukocyte transendothelial migration, levels of neutrophil and monocyte migration were compared among LP and HP isolates A-03, PS-32, and BR-393. As shown in Fig. 2A, HP isolates A-03 and BR-393 induced higher levels of neutrophil migration than did LP isolates. For BR-393, the difference in levels of neutrophil migration stimulated by LP and HP stocks was approximately threefold and found to be statistically significant (*P* < 0.001). In contrast, serial passage of PS-32 in HEP-2 cells did not result in the promotion of higher levels of...
neutrophil migration compared to the LP isolate. Following heat and UV light treatment, stimulation of neutrophil transendothelial migration decreased by averages of 60% and 40%, respectively, compared to live organisms for LP and HP isolates A-03, PS-32, and BR-393.

As depicted in Fig. 2B, serial passage of LP A-03, PS-32, and BR-393 in culture resulted in significant increases of monocyte transendothelial migration compared to mock-infected controls. These increases were approximately threefold for HP A-03 and PS-32 ($P < 0.001$) and twofold for HP BR-393 ($P < 0.05$). A significant difference in the levels of monocyte migration between LP and HP isolates was observed only for A-03 ($P < 0.001$). Compared to live bacteria, heat inactivation inhibited the stimulation of monocyte migration by approximately 90% for LP and HP isolates. Similar results were observed for UV-inactivated A-03, while an average decrease of 75% was obtained with UV-inactivated PS-32 and BR-393.

Effects of passage history on the induction of chemokines by C. pneumoniae in HUVEC. To investigate whether differences in the extent of neutrophil and monocyte migration stimulated by LP and HP C. pneumoniae isolates A-03, PS-32, and BR-393 correlated with differences in chemokine induction, we determined the levels of IL-8 and MCP-1 in infected HUVEC. As depicted in Fig. 3, serial passage of A-03, PS-32, and BR-393 resulted in higher levels of IL-8 and MCP-1 stimulation compared to LP isolates. Levels of IL-8 stimulated by LP and HP...
isolates differed significantly, fivefold for A-03 (P < 0.001) and ninefold for BR-393 (P < 0.05) (Fig. 3A). Differences in MCP-1 levels between LP and HP isolates were approximately 6-fold for A-03 (P < 0.001), 5-fold for PS-32 (P < 0.05), and 13-fold for BR-393 (P < 0.001) (Fig. 3B). Heat inactivation of all C. pneumoniae isolates examined abrogated the induction of IL-8 and MCP-1. Following UV inactivation, the stimulation of IL-8 by LP and HP C. pneumoniae was reduced by approximately 50% for A-03 and remained virtually unchanged for PS-32 and BR-393 compared to viable bacteria. Secretion of MCP-1 in response to PS-32 and BR-393 decreased by an average of 60% for both LP and HP isolates with UV inactivation, while no effect was observed for A-03.

Role of IL-8 and MCP-1 on the stimulation of neutrophil and monocyte transendothelial migration by C. pneumoniae. To examine whether IL-8 and MCP-1 were the major chemo- tactic factors involved in the stimulation of neutrophil and monocyte transendothelial migration by C. pneumoniae, blocking experiments were performed with anti-IL-8 and anti-MCP-1 antibodies. As shown in Fig. 4A, the addition of increasing concentrations of anti-IL-8 to infected HUVEC resulted in a dose-dependent inhibition of neutrophil transendothelial migration, with a significant decrease seen with 20 μg of antibody per ml compared to untreated cells (P < 0.05). Similarly, significant decreases in monocyte migration were observed following anti-MCP-1 treatment of C. pneumoniae-infected HUVEC at both 10 and 20 μg of antibody per ml (P < 0.05) (Fig. 4B). To ensure the specificity of the monoclonal antibodies, anti-MCP-1 and anti-IL-8 at 20 μg per ml were tested for the ability to inhibit neutrophil and monocyte transendothelial migration,
respectively, during the blocking experiments. As shown in Fig. 4, antibodies to MCP-1 and/or IL-8 did not cause significant reductions in neutrophil or monocyte migration compared to C. pneumoniae-infected cells or TNF-α-treated cells that received no antibody.

Levels of neutrophil and monocyte migration across HUVEC infected with C. trachomatis compared to C. pneumoniae. To investigate whether the stimulation of neutrophil and monocyte transendothelial migration was a feature of other Chlamydia species, we performed experiments with C. trachomatis L2 and compared the results to those for C. pneumoniae TW-183 (Table 1). Significant differences in the levels of neutrophil and monocyte transendothelial migration stimulated by C. pneumoniae TW-183 compared to C. trachomatis L2 were observed (P < 0.001). Contrary to results for C. pneumoniae TW-183, we observed only a slight increase in neutrophil migration above the level for mock-infected controls when HUVEC were infected with C. trachomatis L2. As opposed to this low neutrophil migration response, levels of monocyte transendothelial migration were significantly above the mock-infected cell level with C. trachomatis L2 (P < 0.05) and decreased by approximately 30% following UV and heat inactivation.

Secretion of IL-8 and MCP-1 by HUVEC infected with C. trachomatis compared to C. pneumoniae. To examine whether the differences in the extent of neutrophil and monocyte transendothelial migration between C. trachomatis L2 and C. pneumoniae TW-183 correlated with differences in the induction of IL-8 and MCP-1, we measured levels of these chemokines in
infected HUVEC after 24 h of incubation. As depicted in Table 2, contrary to *C. pneumoniae* TW-183, *C. trachomatis* L2 failed to stimulate IL-8 and MCP-1 production from HUVEC. In addition to L2, *C. trachomatis* serovars A and E did not induce secretion of these proteins from infected cells.

**Comparative replication of C. pneumoniae and C. trachomatis in HUVEC.** HUVEC supported replication of all isolates of *C. pneumoniae* examined (both LP and HP), as determined at 48 h postinfection. Growth titers ranged from $6.3 \times 10^3$ to $11.5 \times 10^3$ IFU/ml for the transendothelial migration experiments and $6.5 \times 10^3$ to $9.8 \times 10^3$ IFU/ml for the chemokine experiments. Average growth titers of *C. trachomatis* L2, A, and E were significantly higher than *C. pneumoniae* titers (in migration experiments, $4.6 \times 10^6$ IFU/ml [$P < 0.001$]; in chemokine experiments, $1.7 \times 10^6$ IFU/ml [$P < 0.001$]).

**Lack of a cytotoxic effect following Chlamydia infection in HUVEC.** *C. pneumoniae* and *C. trachomatis* had similar effects on viability of HUVEC after 24 h of infection (>80%), as determined by trypan blue dye exclusion analysis. To further examine whether infection was causing a cytotoxic effect in HUVEC, costimulation experiments were performed with *Chlamydia* species and TNF-α. HUVEC which were initially infected with *C. pneumoniae* or *C. trachomatis* for 24 h were equally capable of responding to exogenous TNF-α (500 U/ml for 24 h) and secreted significant levels of IL-8 and MCP-1 compared to controls. Concentrations of IL-8 and MCP-1 from costimulated cells ranged from 6 to 10 ng/ml and 4 to 7 ng/ml, respectively.

**DISCUSSION**

A number of different methods have been developed to study the interactions of leukocytes and the endothelium, with the purpose of simulating the luminal face of a venular vessel wall during an inflammatory process. In the present study,

a HUVEC monolayers cultured in transwells were inoculated with *C. trachomatis* L2 or *C. pneumoniae* TW-183 at a multiplicity of infection of 1:1. Equivalent inoculum concentrations of each strain were inactivated by heat or UV light before infection (see Materials and Methods). Mock-infected cells were treated with a suspension of lysed HEp-2 cells.

b Levels of neutrophil and monocyte transendothelial migration were determined following 24 h of incubation as described in Materials and Methods. Data represent means ± standard errors of the means of three separate experiments. In each experiment, triplicate wells were assayed separately for each condition for neutrophil and monocyte migration. *, P < 0.05; **, P < 0.01; ***, P < 0.001.

HUVEC were cultured in Transwell-Clear polycarbonate microporous cell culture inserts, which provide independent access to both apical and basolateral sides of the cell monolayer. Using this system, we demonstrated that *C. pneumoniae* promotes the transendothelial migration of neutrophils and monocytes. In addition, heterogeneity of stimulatory activities was observed among different isolates of this organism, and this correlated with differences in the number of passages in HEp-2 cell culture. Overall, HP isolates TW-183 and T-2634 stimulated higher levels of neutrophil and monocyte transendothelial migration compared to LP isolates A-03, PS-32, and BR-393. Serial passage of the LP isolates in HEp-2 cell cultures prior infection of HUVEC generally resulted in higher levels of stimulation of neutrophil and monocyte transendothelial migration. This event correlated with the induction of the neutrophil- and monocyte-specific chemokines IL-8 and MCP-1. As in the leukocyte migration experiments, the extent of IL-8 and MCP-1 secretion elicited by *C. pneumoniae* A-03, PS-32, and BR-393 was dependent on the number of passages in culture before infection of endothelial cells. All *C. pneumoniae* isolates examined in this study exhibited similar replication patterns within HUVEC, and it remains unclear whether the divergence observed among LP and HP isolates reflects intrinsic differences. Possibly, adaptation to HEp-2 cell cultures of recently isolated *C. pneumoniae* strains results in the acquisition or loss of specific features that may be important in the activation of endothelial cells in vitro.

Infection of HUVEC with *C. trachomatis* L2 caused only a slight increase in neutrophil transendothelial migration above the level for mock-infected controls. These results were consistent with IL-8 measurements since this serovar, in addition to *C. trachomatis* serovars A and E, failed to stimulate production of this chemokine from infected HUVEC. Substantial levels of monocyte migration were observed in response to L2 compared to mock-infected controls, although not at the same extent as *C. pneumoniae*, despite a lack of measurable MCP-1 stimulation. These findings may reflect differences in sensitivities between the MCP-1 and monocyte migration assays. Alternatively, chemotactic factors other than MCP-1 may be involved in the monocyte migration response to *C. trachomatis* L2.

The absence of IL-8 and MCP-1 stimulation by *C. trachomatis* L2, A, and E was not a consequence of lack of replication in HUVEC, since growth titers that were significantly higher than *C. pneumoniae*-infected cells were recovered after 48 h of incubation. In addition, significant differences in cell viability between *C. pneumoniae* and *C. trachomatis* were not observed, as determined by trypan blue dye exclusion analysis or the ability of infected HUVEC to respond to exogenous TNF-α. These findings suggest that between these two *Chlamydia* species, the upregulation of IL-8 and MCP-1 in endothelial cells may be unique to *C. pneumoniae*. The possibility exists, however, that the observed differences among species presented herein are due to the cell type used, since previous work has shown induction of IL-8 by *C. trachomatis* L2 in epithelial (30) and monocyte (1) cells.

Results from the blocking antibody experiments suggest that the induction of IL-8 and MCP-1 by *C. pneumoniae* may be the major stimulus responsible for the promotion of neutrophil and monocyte transendothelial migration. Effects of heat and UV inactivation show that viability of this organism is required to stimulate an optimal leukocyte transmigration response. A trend for UV light treatment to reduce the migration of neutrophils and monocytes to a lower extent compared to heat treatment correlated with the chemokine experiments, where UV-inactivated organisms retained a partial ability to stimulate IL-8 and MCP-1 production. Lack of activation of these chemokines by heat-inactivated bacteria has been shown previously (26) and suggests that chlamydial lipopolysaccharide may not be essential in eliciting this response from HUVEC. Alternatively, activation of IL-8 and MCP-1 from these cells may involve a surface-associated molecule in *C. pneumoniae*, such as an outer membrane protein, which is altered by heat but not by UV light treatment.

There is limited information regarding the pathogenesis of *C. pneumoniae* infections in humans, and most data have been derived from animal models. Lung pathology following infection in mice is characterized by inflammation with polymorphonuclear leukocyte infiltration in the early stage and mononuclear cell infiltration in the late stage (37). Dissemination of *C. pneumoniae* to the spleen (25, 38) and aorta (25) has been shown following intranasal inoculation of mice, and recent evidence has demonstrated that this organism is capable of inducing arterial inflammatory lesions resembling atherosclerosis in the aortas of infected rabbits (2, 20). The mechanisms that elicit these responses have not been studied in detail. In

addition to eliciting the expression of chemokines and adhesion molecules in vitro (17, 26), previous work has shown that Chlamydia pneumoniae is capable of activating human endothelial cells to proinflammatory phenotype by enhancing the production of tissue factor (3). Furthermore, Chlamydia pneumoniae is a potent inducer of cytokines such as TNF-α, IL-1, and IL-6 in human monocyte cells (12). These events presumably would play important roles in the immunological response to infection, but they may also promote deleterious effects and contribute to tissue damage.

In summary, Chlamydia pneumoniae causes activation of chemokines in human endothelial cells and promotes the recruitment of leukocytes in vitro. These events may correlate with the pathology described in vivo in animal models of respiratory infection and atherosclerosis. Differences in passage history among cultured cells presumably would play important roles in the immunological response to infection, but they may also contribute to tissue damage.

ACKNOWLEDGMENT

We thank Terri Manning, Division of Nephrology, University of Louisville, for technical assistance in the isolation of neutrophils and monocytes from venous blood of healthy volunteers.
