Biofilm production is thought to be a crucial factor in the ability of *Staphylococcus epidermidis* to produce a biomaterial-based infection. A rat central venous catheter (CVC)-associated infection model was used to assess the importance of biofilm production, mediated by polysaccharide intercellular adhesin/hemagglutinin (PIA/HA), in the pathogenesis of intravascular catheter-associated infection. PIA/HA-positive *S. epidermidis* 1457 was significantly more likely to cause a CVC-associated infection (71 versus 14%, *P* < 0.03) resulting in bacteremia and metastatic disease than its isogenic PIA/HA-negative mutant. These results confirm the importance of biofilm production, mediated by PIA/HA, in the pathogenesis of *S. epidermidis* experimental CVC-associated infection.

*Staphylococcus epidermidis* is the most prominent cause of intravascular catheter-associated infection (28). According to the Centers for Disease Control and Prevention's National Nosocomial Infection Surveillance System, *S. epidermidis* is responsible for 33.5% of nosocomial bloodstream infections (35). These bacteremias are largely due to intravascular catheter-associated infection. Unfortunately, nosocomial bacteremia due to *S. epidermidis* is a rapidly increasing problem and is responsible for significant morbidity and mortality (1, 22, 28).

Bacterial adherence to biomaterials appears to be a pivotal step in the pathogenesis of *S. epidermidis* infections. Adherence occurs in a complex, multistep process (16). The later phases of adherence, in which organisms adhere to one another and elaborate biofilm, are mediated by polysaccharide intercellular adhesin (PIA), which is synthesized by products of the four-gene operon *ica* (12, 17, 21). Recent investigation has revealed that PIA and the hemagglutinin (HA) of *S. epidermidis* are closely related, if not identical (7, 20). In addition, we recently demonstrated the importance of PIA/HA in the pathogenesis of experimental prosthetic device infections in the mouse foreign body infection model. To more closely mimic conditions found in the human intravascular system, a rat model of central venous catheter (CVC)-associated infection was developed and used to test the importance of PIA/HA in the pathogenesis of CVC-associated infection.

(This work was presented in abstract form at the 35th Annual Meeting of the Infectious Diseases Society of America, San Francisco, Calif., 13 to 16 September 1997 [26a]).

The bacterial strains used for these studies were *S. epidermidis* 1457 and a PIA/HA-negative isogenic mutant, *S. epidermidis* 1457-M10. Strain 1457 was isolated from a patient with an infected CVC and has been previously described (21). Strain 1457-M10 is a PIA/HA-negative isogenic mutant of strain 1457 that was produced by insertion of transposon Tn917 at nucleotide 931 in the *icaA* gene of the *icaDABC* gene locus (19, 20).

The rat CVC-associated infection model was used to compare the virulence of *S. epidermidis* 1457 with that of *S. epidermidis* 1457-M10. Fourteen male Sprague-Dawley rats underwent catheterization as previously described (34). Briefly, the surgical area was prepped and draped in a sterile fashion. The neck was surgically dissected and a Silastic lumen-within-lumen catheter (inside diameter, 0.064 cm [34a]) was inserted in the right external jugular vein and advanced into the superior vena cava. The proximal portion of the catheter was tunneled subcutaneously to exit in the midscapular space. The catheter was held in place by a rodent restraint jacket (34b) which simultaneously protected the catheter and allowed ready access to the vein. Twenty-four hours following CVC placement, blood was obtained from the catheters and cultured to ensure sterility, and 10⁶ CFU of *S. epidermidis* 1457 or 1457-M10 was injected into the catheters. The catheters were flushed daily with a heparin solution. On day 8, the animals were sacrificed. Blood from the CVC and the periphery was obtained and quantitatively cultured by directly plating 0.1 ml of blood on Trypticase soy agar (Remel, Lenexa, Kans.). The location of the distal tip of the CVC in the superior vena cava was confirmed, and the catheters and surrounding venous tissue were removed aseptically and vigorously vortex washed in phosphate-buffered saline, after which the wash fluid was quantitatively cultured. Previous studies, in which quantitative culture results were confirmed by electron microscopy, documented complete removal of adherent organisms by this procedure (31). In addition, to ascertain the extent of metastatic disease, the heart, lungs, liver, and kidneys were aseptically harvested, weighed, homogenized in 1 ml of phosphate-buffered saline with sterile disposable tissue grinders (Sage Products, Crystal Lake, Ill.), and quantitatively cultured by plating 0.1 ml of the tissue homogenate on Trypticase soy agar. Bacteria recovered from the catheters, blood, or tissues were identified to the species level.

To limit the number of experimental animals used to the minimum that would reveal a significant difference in pathogenicity, inoculum size experiments were performed. Prior to
the conducting of the comparative studies described above, the smallest inoculum of *S. epidermidis* 1457 that reliably resulted in a CVC-associated infection was determined in dose-ranging inoculum studies. CVCs were placed as described above. Three animals each were challenged with an inoculum of either 10^6, 10^7, or 10^8 CFU of *S. epidermidis* 1457. Following inoculation, the animals were evaluated for the presence of infection as described above.

The chi-square test was used to assess whether there was a significant difference in infection rate between the two groups of animals. The Wilcoxon signed-rank test or Mann-Whitney test was used to analyze data regarding levels of bacteremia and metastatic disease. Statistical tests were performed with Prism 2.0 (Graphpad, San Diego, Calif.).

The inoculum studies showed that all of the animals inoculated with 10^6 or 10^7 CFU of *S. epidermidis* 1457 developed CVC-associated infection with metastatic disease (data not shown). One of the animals inoculated with 10^5 CFU of *S. epidermidis* 1457 had organisms recovered from the CVC, blood, and lungs. The other two animals did not develop a CVC-associated infection. Therefore, the 10^5-CFU inoculum size, the lowest dose which reproducibly caused CVC-associated infection and metastatic disease, was used in the larger comparative trial.

The overall infection rate, defined as recovery of *S. epidermidis* from the blood, catheter, or organs at the time of sacrifice, is shown in Fig. 1. More rats challenged with the wild-type strain developed CVC-associated infection than did those challenged with the PIA/HA mutant strain (71.4 versus 14.3%; *P* = 0.03, chi-square test).

Five of the seven animals challenged with *S. epidermidis* 1457 had organisms recovered from the CVC at the time of sacrifice (mean ± standard deviation, 195 ± 92 CFU per catheter), compared to none of the seven animals challenged with the mutant strain 1457-M10 (*P* < 0.0001, chi-square test).

Four of the seven animals challenged with *S. epidermidis* 1457 had organisms recovered from the peripheral blood at the time of sacrifice (976 ± 413 CFU per ml), compared to one of the seven animals challenged with strain 1457-M10 (100 CFU per ml) (*P* = 0.02, Wilcoxon signed-rank test).

Table 1 summarizes results from studies defining the burden of metastatic disease in animals challenged with either *S. epidermidis* 1457 or 1457-M10. For all organ systems, there were more animals with metastatic disease in the group challenged with strain 1457 than in the group challenged with strain 1457-M10. In addition, for all organ systems, the number of organisms recovered per gram of tissue was greater in the animals challenged with 1457 than in those challenged with 1457-M10. However, these differences were not statistically significant.

Bacterial adherence to biomaterials is thought to be a pivotal event in the pathogenesis of intravascular catheter-associated infections and infections with other prosthetic medical devices. It appears that bacterial adherence is a complex multistep process that is influenced by the host, the device, and the microbe. Cristina conveniently subdivided the adherence process into the following stages: attachment, adhesion, and aggregation (9). Aggregation, the final stage of adherence, is characterized by the formation of multicellular macrocolonies and elaboration of biofilm. It has long been suspected that staphylococcal biofilm, also known as slime, is important in the pathogenesis of biomaterial-based infections (2, 4, 26). Biofilm appears to function in the later, aggregative stages of adherence and may serve to protect the organisms from host phagocytic cells and improve the local nutritional environment (9). Unfortunately, until the development and application of molecular genetic techniques, the data regarding the importance of biofilm conflicted (3). Epidemiologic studies, clinical observations, and animal model studies were contradictory. For example, Christensen and coworkers, using a mouse foreign body infection model, found that a biofilm-producing strain of *S. epidermidis* caused three times more infections than a non-biofilm-producing strain (5). Conversely, Patrick and colleagues, using the same model, observed that although biofilm-producing *S. epidermidis* strains adhered to catheters in greater numbers than non-biofilm-producing strains, they were less likely to cause a clinically evident infection (24). Likewise, efforts to biochemically characterize biofilm were fraught with difficulty (6).

More recently, techniques to genetically manipulate *S. epidermidis* have been improved, and a number of specific factors related to biofilm have been described. PIA, described by Mack and colleagues, is synthesized by the gene products of the icaADBC locus, the genes of which are organized in an operon structure (8, 12, 17, 21). PIA is a polysaccharide that is elaborated by the majority of clinically significant strains of *S. epidermidis* (17, 18, 36). Isogenic, PIA-negative Tn917 insertional mutants are capable of attachment to biomaterials but are unable to form multilayer macrocolonies or to produce biofilm (19). The HA of *S. epidermidis* has also been observed in the majority of clinically relevant strains and is composed of carbohydrates (27, 30). HA appears to play a role in adherence (15, 27, 29, 30), and recent phenotypic and genotypic characterizations revealed that PIA and HA are closely related, if not identical (7, 20). In addition, a 140-kDa extracellular protein that appears to be involved in cellular aggregation and biofilm formation has been described (13). A number of investigators have described factors that appear to be significant in the early stages of adherence. These include a polysaccharide adhesin (PSA) described by Tojo and coworkers (33) and a 148-kDa proteinaceous autolysin described by Heinlmann and colleagues (10, 11). Recently, data indicating that the ica locus may also

*Differences were not significant, as determined by the Mann-Whitney test.*
encode production of PSA and that PSA mediates both initial adherence and aggregation were reported (23).

Because of the complexity of the milieu surrounding implanted prosthetic medical devices, it is difficult to duplicate these conditions in vitro models, and it is desirable to test hypotheses related to pathogenesis in vivo models that reflect the human condition. We recently demonstrated the importance of PIA/HA in a mouse foreign body infection model (31). However, this model does not accurately reflect the dynamics of the intravascular environment, and thus we developed the rat CVC-associated infection model. This model makes use of a rat CVC and a rodent restraint jacket that allows for long-term venous access and mimics the condition found in surgically implanted CVCs in humans, such as Hickman or Broviac catheters. Our model differs from other models used to study staphylococcal prosthetic device infection pathogenesis in several important respects. As mentioned above, the mouse foreign body model does not involve the vascular space. Consequently, features such as blood flow dynamics, serum proteins and other blood components, and humoral immunity are not accurately reflected. Tissue cages have been used in guinea pigs and other animal species to study the interaction between microbes and biomaterials (37). However, the limitations noted for the mouse foreign body model also apply to the tissue cage models. A number of investigators have used the rabbit model of endocarditis to study putative virulence determinants of coagulase-negative staphylococci. However, the model relies on a foreign body placed across the heart valve to induce endothelial damage and involves the arterial circulation. Coagulase-negative staphylococci are a very rare cause of native valve endocarditis, and therefore, this model may not be the optimum model to study the pathogenesis of infections caused by these organisms. Factors that predispose bacteria to adherence to damaged endothelial cells and contribute to the propagation of cardiac vegetations may not be the same factors that mediate both adherence to biomaterials and the formation of biofilms on prosthetic devices. Also, catheterization of the high-pressure arterial system may not reflect conditions in the venous system. These factors may explain why Perdreau-Remington et al. noted that chemically induced mutants deficient in biofilm formation showed no decreased virulence in the rabbit endocarditis model (25). Also, it has been demonstrated that the mutant M7, used in those studies, is capable of PIA production (13). A model that closely approximates human CVC-associated infection was employed by Kojima and colleagues to study the protective value of antibody directed against PSA (14). In this rabbit CVC-associated infection model, rabbits underwent implantation of jugular venous catheters that were seeded with bacteria. The catheters were connected to subcutaneously implanted osmotic pumps that delivered a continuous flow of heparin solution. Antibody against PSA appeared to protect the animals from the development of bacteremia. PSA is a capsular polysaccharide that appears to play a role in the early stages of adherence (32, 33). PSA-deficient transposon mutants were also less virulent in the rabbit endocarditis model (32).

The rat model utilized in this study appears to mimic the human condition. In this model we demonstrated that PIA/HA is important in the pathogenesis of CVC-associated infection. Isogenic, PIA/HA-deficient mutants caused lower overall infection rates, were recovered in lower numbers from the implanted catheters and the bloodstream, and caused less metastatic disease than the wild-type parent strain. These observations may be due to the inability of the PIA/HA-negative mutant to form macrocolonies in the aggregate stage of adherence or may be secondary to the immunologic or nutritional properties of biofilm. Although the burden of metastatic disease was greater in animals infected with the wild-type strain of Staphylococcus epidermidis, the differences did not reach statistical significance. Several explanations are possible. First, the number of animals simply may not have been great enough to demonstrate significance in the secondary measures of CVC-associated infection (primary endpoints being organisms recovered from the CVC and blood). Alternatively, once the CVC is infected, there may not be differences in virulence. PIA/HA may not influence metastatic seeding of organs which may be secondary to as yet undefined non-specific factors.

The pathogenesis of prosthetic device infections is a complex process in which bacterial adherence to biomaterials and elaboration of biofilm are crucial. Future work should be directed at increasing the understanding of how the various adhesins and putative virulence determinants interplay to result in a prosthetic device infection.
