Received 10 June 1999/Returned for modification 16 July 1999/Accepted 20 October 1999

Entry of opsonized pathogens into phagocytes may benefit or, paradoxically, harm the host. Opsonization may trigger antimicrobial mechanisms such as reactive oxygen or nitric oxide (NO) production but may also provide a safe haven for intracellular replication. Brucellae are natural intramacrophage pathogens of rodents, ruminants, dogs, marine mammals, and humans. We evaluated the role of opsonins in *Brucella*-macrophage interactions by challenging cultured murine peritoneal macrophages with *Brucella melitensis* 16M treated with complement- and/or antibody-rich serum. Mouse serum rich in antibody against *Brucella* lipopolysaccharide (LPS) (aLPS) and human complement-rich serum (HCS) each enhanced the macrophage uptake of brucellae. Combinations of suboptimal levels of aLPS (0.01%) and HCS (2%) synergistically enhanced uptake. The intracellular fate of ingested bacteria was evaluated with an optimal concentration of gentamicin (2 µg/ml) to control extracellular growth but not kill intracellular bacteria. Bacteria opsonized with aLPS and/or HCS grew equally well inside macrophages in the absence of gamma interferon (IFN-γ). Macrophage activation with IFN-γ inhibited replication of both opsonized and nonopsonized brucellae but was less effective in inhibiting replication of nonopsonized bacteria. IFN-γ treatment of macrophages with opsonized or nonopsonized bacteria enhanced NO production, which was blocked by Nω-monomethyl l-arginine (MMLA), an NO synthesis inhibitor. MMLA also partially blocked IFN-γ-mediated bacterial growth inhibition. These studies suggest that primary murine macrophages have limited ability to control infection with *B. melitensis*, even when activated by IFN-γ in the presence of highly opsonic concentrations of antibody and complement. Additional cellular immune responses, e.g., those mediated by cytotoxic T cells, may play more important roles in the control of murine brucellosis. 

*B. melitensis* usually infects sheep, goats, and camels and is the most pathogenic species for humans (1). Like other facultative intracellular pathogenic bacteria (*e.g.*, *Francisella tularensis*, *Listeria monocytogenes*, *Mycobacterium* spp., and *Legionella pneumophila*), clearance of *Brucella* infection relies on both cell-mediated immunity (1, 3, 7, 12, 20, 21, 27, 30, 38) and humoral responses (10, 22, 29, 35). The interplay of these two arms of the immune response, however, is not well understood. Successful infection of the host by *Brucella* reflects the ability of the bacterium to establish itself in an intracellular environment favorable for its replication. The presence of complement or antibody in the extracellular fluid favors killing of some *Brucella* strains (35, 38). Opsonization by these humoral factors also enhances uptake by phagocytic cells that shelter the bacteria. The intracellular fate of brucellae may depend on the bacterial species or the kind of phagocyte ingesting them. For example, opsonization with complement in vitro leads to uptake and killing of *Brucella abortus* by human neutrophils whereas the more virulent *B. melitensis* survives under these conditions (38). Similarly, *B. abortus* opsonized with antibody containing fresh or heated bovine serum induces the production of oxidative products in bovine neutrophils (6). Although neutrophils represent an important first line of defense against brucellae, the longer-lived mononuclear phagocyte is the more important effector cell for defense against established infection (1). Bovine blood monocyte-derived macrophages (MDM) ingest more *B. abortus* bacteria when opsonized with complement-rich bovine serum than with serum rich in both antibody and complement (4), suggesting that complement plays a more important role than specific antibody in uptake and killing of *B. abortus* by these bovine blood MDM.

In macrophage-pathogen interactions, complement receptors (CR) and complement (2, 3, 27) mediate uptake of intracellular pathogens like *L. pneumophila* (2, 3, 27), *Mycobacterium tuberculosis* (32, 33), and *Leishmania donovani* (3). Ligation to CR does not normally trigger the oxidative burst in phagocytes (33, 36, 37). Consequently, intracellular pathogens gain entry to the cell without the generation of reactive oxygen species, enhancing their survival within host cells (27, 32). A number of investigators (10, 11, 14, 16, 18) have opsonized *Brucella* with antiserum to ensure the infection of macrophages during in vitro studies. Gross and associates (14) recently showed...
that both nonopsonized and antibody-opsonized *Brucella suis* strains induce mRNA for inducible nitric oxide (NO) synthase (iNOS) in the mouse macrophage-like J774A.1 cell line. However, only antibody-opsonized *B. suis* triggers NO production. Gamma interferon (IFN-γ)-induced, NO-mediated bacteriostasis occurs preferentially if brucellae are opsonized with antibody (14). The contribution of opsonins to the fate of ingested *B. melitensis*, however, has not been systematically examined. In addition, the interplay of opsonins and macrophage-activating factors in the clearance of brucellae from primary macrophages rather than cell lines, is unknown.

Endogenous IFN-γ (39) and interleukin-12 (40) can mediate protective immunity to *B. abortus* infections in CBA/J mice. Treatment of these mice with anti-interleukin-12 increases splenic bactericidal activity in proteose-peptone-elicited mouse peritoneal macrophages. This controversy is reminiscent of the controversies enshrouding NO dependence in the control of secondary *L. monocytogenes* infection in CBA/J mice (31) and NO involvement in macrophage candidacidal potency (34).

In this report, we demonstrate effective ingestion of virulent *B. melitensis* 16M by adult mouse peritoneal macrophages in the presence of immune serum or human complement-rich serum (HCS). Combinations of slightly effective concentrations of immune serum and HCS are synergistic in this in vitro system. Once internalized, the brucellae grow well in resting (nonactivated) macrophages whether or not the bacteria were previously exposed to opsonins. Activation of macrophages with IFN-γ leads to NO production and inhibition of bacterial growth. IFN-γ-mediated antibacterial activity is partially inhibited by addition of N\(^\circ\)-monomethyl L-arginine (MLLA).

### MATERIALS AND METHODS

**Media.** DME-FBS medium contained 10% fetal bovine serum (FBS) (HyClone) and 2 mM l-glutamine in Dulbecco’s modified Eagle’s medium (DME) (BioWhittaker, Walkersville, Md.). DME-FBS-MCSF medium consisted of DME-FBS with 40 ng of recombinant human macrophage colony-stimulating factor per ml, kindly provided by Dr. J. Stoudemire, Genetics Institute, Cambridge, Mass. L-Arginine was present in DME at a concentration of 0.4 mM, except where otherwise indicated.

**HCS.** Fresh normal HCS was obtained from a seronegative (by tube agglutination test) adult volunteer. Venous blood was drawn into a vacuum bottle and allowed to clot at room temperature for about 30 min. It was then centrifuged for 20 min at 4°C and at 1,800 × g. Serum was aliquoted and stored at −70°C until use (usually within 3 months). Aliquots were thawed and used once.

**Antiserum.** Anti-lipopolysaccharide (LPS) serum (aLPS) was obtained by immunizing BALB/c mice with a mixture of *B. abortus* and *B. melitensis* LPS (10 μg of each LPS/dose) subcutaneously. Two doses of vaccine were administered 4 weeks apart, and the mice were bled 2 weeks after the second dose. Sera from 5 mice were pooled. Antibody titers to *B. melitensis* LPS, determined by enzyme-linked immunosorbent assay, were 1:6,000.

**Bacteria.** For macrophage challenge, 16M was grown in *Brucella* broth for 24 h in shaker flasks. Bacteria were pelleted by centrifugation, washed once in 0.9% NaCl, and resuspended to approximately 2 × 10\(^6\) bacteria/ml in 0.9% NaCl. The actual number of viable organisms was determined in reverse trial through dilution and plating for CFU.

**Isolation, purification, and bacterial infection of mouse peritoneal macrophages.** Peritoneal cells were isolated from 8- to 16-week-old female BALB/c mice (Jackson Laboratories, Bar Harbor, Maine) by lavage with 10 ml of ice-cold Ca\(^2+\)-Mg\(^2+\)-free Hanks balanced salt solution (BioWhittaker). The peritoneal cells were pelleted, resuspended in DME-FBS-MCSF, and plated in 96-well polypropylene microtiter plates (Costar, Cambridge, Mass.) at 0.125 × 10\(^5\) macrophages per well. The cultures were incubated overnight at 37°C and 5% CO\(_2\). The supernatant was aspirated and the adherent macrophage monolayer was washed three times with 37°C DME-FBS and finally covered with 45 μl of DME-FBS-MCSF, with or without HCS or aLPS. Five microliters of aLPS suspension giving a multiplicity of infection (MOI) of 8 was added and cultures were returned to the incubator for 1 h. The concentrations of serum used in these experiments did not cause bacterial agglutination by light microscopy or tube testing. After 1 h at 37°C, the supernatant fluid containing extracellular bacteria was removed and the monolayer was washed three times with 100-μl aliquots of DME-FBS. Monolayers were either lysed to obtain 1-h bacterial counts as described below or replenished with 200 μl of DME-FBS-MCSF routinely containing gentamicin at a concentration of 2 μg/ml. In some instances, this latter medium was supplemented with 10 U of recombinant murine IFN-γ per ml, with or without 1 mM MMLA, a competitive inhibitor of all three forms of L-arginine-dependent NO synthase. Cultures were incubated for 48 h before lysis for determination of bacterial counts. Cultures were inspected by light microscopy before lysis. All monolayers remained intact and cells appeared healthy throughout the 48-h culture period. In preliminary experiments, recombinant human macrophage colony-stimulating factor was required for preservation of the monolayers (data not shown).

**Determination of bacterial burden (intracellular CFU) in macrophages.** At appropriate times of incubation in fresh medium after the initial 1-h infection period, bacterial burden was determined as follows: Triton X-100 was added directly to the 200-μl culture (final concentration, 0.1%) to lyse the macrophages. The number of CFU in lysates was determined by serial dilutions and plating on Brucella agar as previously described (8), without separation of supernatants from adherent cells. We had previously determined that, within the short period (10 min) of lysis under these conditions, the 2 μg of gentamicin/ml present in the culture medium did not affect the viability of brucellae liberated to the medium (data not shown).

**NO production.** The NO content of culture supernatants was estimated by analysis of nitrite (product of rapid oxidation of NO in aqueous solution) with the Griess reagent (13).

**Synergy of complement and antibody.** Combining suboptimal concentrations of HCS (2%) with aLPS (0.01%) had a synergistic effect on bacterial uptake (Fig. 2). There was a 3.2-fold increase in the number of CFU recovered when brucellae were treated with the 2% HCS–plus–0.01% aLPS combination, as compared to the sum of the CFU when bacteria were treated with 2% HCS or 0.01% aLPS alone. At optimal concentrations of either antibody or HCS for infection of macrophages, no synergy between HCS and antibody occurred (data not shown). These observations were consistent with a cooperative antibody and complement-mediated uptake of brucellae at suboptimal levels of either reagent. They further indicated that similar maximal levels of bacterial uptake could be achieved by treatment of bacteria with antibody, complement, or both.

**Effects of gentamicin on recovery of bacteria from macrophages during prolonged culture.** Since 16M grows in tissue culture medium at least as well as it does inside macrophages, analysis of the fate of intracellular brucellae for more than the short periods of time required for uptake requires the addition of antibiotics to the medium. Aminoglycosides have tradition-
further evidenced over the next day of culture. At 0 and 2

dose-related reduction in the number of intracellular CFU at
both 30 min and 24 h (Table 1). This bactericidal effect was
further evidenced over the next day of culture. At 0 and 2 µg
of gentamicin per ml, the number of intracellular bacteria
increased by 19 and 27%, respectively, from 30 min to 24 h,
while at a concentration of 10 or 100 µg of gentamicin per ml,
the number of intracellular CFU declined by 45 and 77%,
respectively (Table 1).

To verify that these low levels of gentamicin, which did not
inhibit intracellular replication, were sufficient to inhibit extracellular replication, we examined the number of CFU/ml in

* Peritoneal macrophages were infected with 16M without opsonins and extracellular bacteria were washed off. Monolayers were replenished with 200 µM of DME-FBS-MCSF containing gentamicin at a concentration of 0, 2, 10, or 100 µg/ml. After 30-min or 24-h incubation, the culture medium was removed and the monolayers were washed three times before lysing and plating to determine the number of CFU. Data in Table 1 show that gentamicin at a concentration of 2 µg/ml was safe for intracellular B. melitensis 16M during long-term incubation. Gentamicin at 2 µg/ml did not significantly affect the number of CFU/well among cultures incubated for 30 min or 24 h (P = 0.17 and P = 0.55, respectively, with respect to cultures incubated without antibiotics). In contrast, culture with 10 or 100 µg of gentamicin per ml led to a significant (P < 0.05 to P < 0.008) dose-related reduction in the number of intracellular CFU at both 30 min and 24 h (Table 1). This bactericidal effect was further evidenced over the next day of culture. At 0 and 2 µg of gentamicin per ml, the number of intracellular bacteria increased by 19 and 27%, respectively, from 30 min to 24 h, while at a concentration of 10 or 100 µg of gentamicin per ml, the number of intracellular CFU declined by 45 and 77%, respectively (Table 1).

To verify that these low levels of gentamicin, which did not inhibit intracellular replication, were sufficient to inhibit extracellular replication, we examined the number of CFU/ml in supernatants at 48 h in cultures that received 0 to 4 µg of gentamicin per ml after the 1-h infection period (Table 2). In cultures without antibiotics, >540,000 CFU/well were found in supernatants. This number was reduced at least 30-fold by culture with 1 µg of gentamicin per ml and at least 500-fold by culture with 2 µg of gentamicin per ml. In the presence of 1 to 4 µg of gentamicin per ml, the percentage of total CFU/well attributable to bacteria present in the supernatant was less than 5% for 1 µg of antibiotic per ml and less than 1% for a concentration of 2 or 4 µg/ml. There was no difference in total CFU/well among cultures incubated with 1 to 4 µg of gentamicin per ml. Treatment with IFN-γ caused a similar inhibition of replication in cultures treated with all three antibiotic concentrations. These studies indicated that gentamicin concentrations between 1 and 4 µg/ml were sufficient to control extracellular bacterial replication but not so high as to kill...

*Peritoneal macrophages were infected with 16M without opsonins and extracellular bacteria were washed off. Monolayers were replenished with DME-FBS-MCSF containing indicated concentrations of gentamicin with or without IFN-γ. After 48 h of incubation, B. melitensis CFU in culture supernatants (extracellular 16M) were determined by serial dilution and plating of supernatants on Brucella agar. The number of intracellular bacterial CFU was determined by lysis of monolayers followed by serial dilution and agar plating.

†Values are the mean ± SEM CFU/well from five replicate wells from one of two similar experiments.

Increased in number over this period. In the results shown in Table 3, 16M opsonized with aLPS, HCS, or a combination of HCS and aLPS grew about 30-fold more rapidly than nonopsonized 16M in macrophages that had not been treated with IFN-γ. In three additional experiments, growth of nonopsonized bacteria in the absence of IFN-γ ranged from 55- to 149-fold. Bacteria opsonized with HCS with or without aLPS alone grew 27- to 139-fold, while those opsonized with aLPS alone grew 48- to 434-fold. Addition of IFN-γ to macrophage cultures immediately after infection inhibited bacterial growth but did not reduce the number of CFU below the levels at 1 h. Inhibition occurred regardless of whether brucellae had previously been opsonized. In the experiment shown in Table 3, culture with IFN-γ led to 53% anti-Brucella activity for nonopsonized bacteria and 68 to 89% activity for opsonized bacteria. In three additional experiments, IFN-γ-mediated anti-Brucella activity ranged from 49 to 75% for nonopsonized organisms and 55 to 87% for opsonized organisms. In each of these experiments, IFN-γ-mediated anti-Brucella activity was always greater for each category of opsonized compared to nonopsonized organisms. The choice of opsonin (either aLPS or HCS alone or aLPS plus HCS) did not consistently affect the intensity of this activity (data not shown). By linear regression analysis, fold increase in bacteria in non-IFN-γ-treated cultures did not correlate (P > 0.1) with percent IFN-γ-mediated anti-Brucella activity over all four experiments (r = 0.404; t = 1.654; n = 16).

The involvement of nitric oxide. Both NO (14, 17, 40) and reactive oxygen intermediates (17) mediate macrophage anti-Brucella effects. To examine the role of NO in the IFN-γ-mediated anti-Brucella activity described above, we infected macrophages with opsonized brucellae, treated them with IFN-γ in the presence or absence of MMLA in the presence of 0.8 mM L-arginine (twice the concentration in our standard medium), and determined nitrite levels and the number of bacterial CFU (Fig. 3). Macrophages cultured without brucellae or cultured with brucellae but without IFN-γ made ≤0.3 nmol of nitrite/200 μl well (i.e., ≤1.5 μM). Addition of IFN-γ to macrophages cultured without brucellae did not enhance NO production, but NO production by macrophages cultured with bacteria and IFN-γ was profoundly enhanced (≥10-fold). Addition of MMLA, which completely abrogated NO production, had inconsistent effects on IFN-γ-mediated anti-Brucella activity (Fig. 3). There was no difference in anti-Brucella activity in MMLA-treated cultures compared to untreated cultures in which brucellae had been opsonized with aLPS plus HCS, but partial MMLA-induced inhibition occurred in cultures in which brucellae had been opsonized with aLPS or HCS alone.

a Macrophage monolayers were incubated with 8 bacteria per macrophage with or without 0.001% aLPS and HCS or with a combination of 0.01% aLPS and 2% HCS. Controls received DME-FBS-MCSF medium but without opsonin. The number of intracellular bacteria was determined by lysis of monolayers after 1 and 48 h, followed by serial dilution and plating on agar.

b Mean ± SEM CFU per well from five replicate wells in one of four similar experiments.

c Numbers in parentheses represent the ratio of CFU at 48 h to CFU at 1 h.

d[(CFU minus IFN-γ) – CFU (plus IFN-γ)]/[CFU (minus IFN-γ)] × 100.
Data are the mean ± SEM CFU in each well from five replicate wells. As shown by others for *B. abortus* and *B. melitensis* (14), IFN-γ-activated macrophages exerted greater inhibition on the growth of opsonized brucellae than nonopsonized bacteria. It is possible that the relative ineffectiveness of IFN-γ-treated macrophages against nonopsonized bacteria was due to the reduced uptake of nonopsonized organisms and the consequent failure of the fewer ingested bacteria to trigger the release of adequate antimicrobial effector molecules. It is also possible that engagement of macrophage FcR or CR by opsonized brucellae triggers antimicrobial effector responses.

From their work with scavengers and inhibitors of reactive oxygen species, Jiang and associates concluded (17) that superoxide (O$_2^-$) and hydrogen peroxide (H$_2$O$_2$) might contribute to control of *B. abortus* in elicited mouse peritoneal macrophages, whereas NO was of less importance in the process. For several intracellular pathogens, a lack of correlation in the effects of varying NO levels (with NO synthase inhibitors or NO donors) on bacterial clearance has been described (34). Synergy between the receptor for the Fc domain of immunoglobulin G (FcR) and the receptor for C3b, a cleavage product of C3 (C3bR), for the uptake of opsonized sheep erythrocytes is well described (25). Synergy in the uptake of intracellular pathogens may involve a combination of additional phagocyte receptors which, on binding ligand, almost always trigger internalization (such as FcR and the mannose receptors) and those that sometimes fail to trigger ingestion (e.g., CR) (19, 25, 33). Thus, virulent strains of *M. tuberculosis* are phagocytosed by the cooperation of CR and mannose receptors on human MDM, whereas attenuated strains are internalized by the function only of CR (33). Interestingly, the O-polysaccharides of smooth brucellae have an abundance of mannosyl residues (1, 5) but resist phagocytosis in the absence of opsonins.

Treatment of *B. abortus* with complement-rich serum prior to exposure to human neutrophils leads to extracellular and intracellular killing of bacteria, but similar treatment of *B. melitensis* does not lead to killing (38). Cheers and Ho (7) reported an increased uptake of antibody-opsonized *L. monocytogenes* in mice. Opsonization with antibody did not alter the growth of this organism once it was inside the liver and spleen cells. On the other hand, clearance of *Salmonella enterica* serovar Typhimurium and *B. abortus* early in infection increased with opsonization with specific antibody. It was therefore concluded that a nonspecific cellular mechanism was responsible for early enhanced resistance to each infection (7). Our data show that resident mouse peritoneal macrophages, like human neutrophils, fail to kill *B. melitensis*. As shown by others for *B. abortus* (16) and *B. suis* (14), IFN-γ-activated macrophages exerted greater inhibition on the growth of opsonized brucellae than nonopsonized bacteria. It is possible that the relative ineffectiveness of IFN-γ-treated macrophages against nonopsonized bacteria was due to the reduced uptake of nonopsonized organisms and the consequent failure of the fewer ingested bacteria to trigger the release of adequate antimicrobial effector molecules. It is also possible that engagement of macrophage FcR or CR by opsonized brucellae triggers antimicrobial effector responses.

From their work with scavengers and inhibitors of reactive oxygen species, Jiang and associates concluded (17) that superoxide (O$_2^-$) and hydrogen peroxide (H$_2$O$_2$) might contribute to control of *B. abortus* in elicited mouse peritoneal macrophages, whereas NO was of less importance in the process. For several intracellular pathogens, a lack of correlation in the effects of varying NO levels (with NO synthase inhibitors or artificial NO donors) on microbial burden has led to different conclusions regarding the role of NO as an antipathogen effector. For example, murine macrophage NO may act alone or cooperate with other macrophage microbicidal mechanisms to kill *Candida* (34). For *L. monocytogenes*, murine macrophage NO may play a direct listericidal role in primary infections but may be of less importance in secondary infections (31). In contrast to the studies of Jiang et al. (17), Gross and associates (14) have shown that NO is involved in the elimination of *B. suis* from murine cells, provided that both *Brucella* antibodies and IFN-γ are present. Nonopsonized bacteria did not trigger...
the production of iNOS or NO, although they did enhance iNOS mRNA levels. Our data most closely resemble those of Jiang et al. (17), in that peritoneal macrophages treated with IFN-γ shortly after infection modestly inhibited the growth of Brucella and the intracellular growth of bacteria in both IFN-γ-treated and control cells was enhanced by the addition of MMLA. The failure of treatment with MMLA to completely reverse the anti-Brucella effect of IFN-γ in both of our studies indicates that factors other than NO must play a predominant role in intramacrophage killing. It is more difficult to compare our data with those of Gross et al. (14), since they used only J774A.1 cells and B. suis, while we used resident peritoneal cells with B. melitensis. It is possible that B. suis is more susceptible to NO-mediated killing than B. melitensis or B. abortus. Alternatively, B. suis may induce higher levels of NO in IFN-γ-treated cells than the other Brucella species. In our system, the levels of NO induced were approximately 1/2 of those induced by B. suis in the studies of Gross et al. (14). The failure of any of these systems to induce the clearance of bacteria from macrophages may be related to failure to achieve the consistent levels of NO actually required to kill bacteria from macrophages may be related to failure to achieve the consistent levels of NO actually required to kill Brucella. Strategies that induce more NO production, or favor cooperation between reactive oxygen and reactive nitrogen to produce more potent antimicrobial moieties such as peroxynitrite (15), may remedy this deficiency.

Our culture systems also differ from those of others (10, 11, 14, 16–18) in the concentration of antibiotics used to control the extracellular growth of Brucella. Gentamicin concentrations of ≥50 µg/ml were used in these previous studies to induce rapid killing of extracellular brucellae at the end of the initial infection period. These high concentrations were justified because rapidity of killing by aminoglycosides is related to dose. In standard mean inhibitory concentration or mean bacterial concentration assays, brucellae are sensitive to 1 to 4 µg of gentamicin per ml (23). These data are consistent with our observations that ≥1 µg of gentamicin/ml was sufficient to prevent growth of 16M over 48 h. In our system, repeated washing of monolayers after the initial 1-h period of infection reduces the number of recoverable extracellular bacteria to ≤100 CFU/well (data not shown). It is possible that the use of high concentrations of antibiotics in previous studies contributed to the decline in CFU in the first 24 h after infection of macrophages with opsonized or nonopsonized bacteria observed by those authors. It is possible that recently ingested bacteria present in membrane-bound compartments are susceptible to gentamicin that penetrates macrophages when it is present in culture fluids at high concentrations (9). After some endosomal maturation has occurred, bacteria may be protected from intramacrophage gentamicin, so growth resumes, even if high aminoglycoside levels are maintained in the culture medium. Trafficking of Brucella-containing phagosomes consistent with this hypothesis has recently been demonstrated in HeLa cells (28). Whether inclusion of high doses of antibiotics in the studies cited influences the anti-Brucella activity attributed to IFN-γ is unknown but must be considered in the interpretation of apparently conflicting results.

These studies are important in light of the consistent observation that the presence of antibody to Brucella, whether derived by active or passive immunization, leads to profound anti-Brucella effects (1, 7, 10, 22, 29, 35) in vivo. Our data suggest that, even when brucellae are opsonized with antibody and complement, the IFN-γ-mediated activation of resting macrophages inhibits the intracellular growth of B. melitensis but does not result in the clearance of organisms from their intracellular niche. These studies support the conclusion that additional cellular immune responses, e.g., those mediated by cytotoxic T cells (26), may also play important roles or that additional signals are provided in vivo to further enhance macrophage brucellacidal activity. We are currently examining mechanisms of antibody effects in vivo with a murine model of intranasal infection with B. melitensis.
