Rabbits orally challenged with \textit{Salmonella enterica} developed a dose-dependent diarrheal disease comparable to human salmonellosis. Viable \textit{Salmonella} organisms recovered from the intestine and deep tissues indicate local and systemic infections. Therefore, results show that the rabbit can be used as a model for diarrheal disease and sequelae associated with salmonellosis.

\textit{Salmonella enterica} serotypes are the leading causes of foodborne illness worldwide (3), with approximately 50% of human infections caused by the serotypes Enteritidis and Typhimurium (4). Over 30\% of \textit{Salmonella enterica} serotype Typhimurium isolates are in the DT-104 phage type complex and exhibit the classic five-drug pattern of resistance (9). An infection with an \textit{S. enterica} serotype generally causes a localized intestinal infection or gastroenteritis characterized by a sudden onset of abdominal pain and loose, watery diarrhea, occasionally with mucus or blood (11). In localized infections, the organisms invade the intestinal wall but remain predominantly within gut tissue and the local lymphatics. However, \textit{S. enterica} serotypes can spread systemically in the elderly, in young children, and in immunocompromised individuals. Reports from the United Kingdom suggest that infection with five-drug-resistant serotype Typhimurium may result in greater morbidity and mortality than infection with other serotypes (9).

The murine enteric fever model has been extensively utilized to evaluate \textit{Salmonella} pathogenicity. However, the lack of diarrheal disease in this model is limiting for the study of foodborne illness. Collins and Carter (6) have shown that germfree mice develop diarrhea when they are orally challenged with as few as 10 CFU of \textit{Salmonella enterica} serotype Enteritidis and that they die within 8 days of challenge. Although these animals develop diarrhea, they may not be representative of conventional animals. Surgical models that measure fluid accumulation as an indication of diarrheal disease caused by \textit{S. enterica} serotypes have been developed with large animal species (1, 5, 10, 13), and several nonsurgical models for diarrheal disease have been developed with pigs (15, 20), calves (18, 19, 21), ponies (16), and primates (12, 17). However, these animals are not readily available in a standard animal facility, and therefore the usage of large numbers for in-depth studies is precluded. \textit{Salmonella} virulence has also been examined using ligated rabbit or isolated intestinal sections (2, 5, 8). Although these models have been valuable for identifying \textit{Salmonella} strains and genes that induce fluid accumulation, these surgical models do not represent the desired model, which would demonstrate the route and course of infection seen with food-borne salmonellosis.

This work describes a nonsurgical, oral challenge rabbit model for salmonella gastroenteritis. Rabbits develop a dose-dependent diarrheal illness that is comparable to that seen in human salmonellosis. A multidrug-resistant strain of \textit{S. enterica} serotype Typhimurium phage type DT-104b, designated DT-9, which was isolated from children in a day care center, was used as the primary salmonella isolate. An outbreak-associated strain was chosen since the focus of this model is to emulate symptoms seen with food-borne salmonellosis.

Overnight cultures of salmonellae grown at 37°C in Luria-Bertani (LB) broth in a microaerophilic environment were used for all challenge studies. All cultures were serially diluted 10-fold in LB broth immediately before challenge, and their inoculum size was confirmed by plate counts. The killed salmonella controls were inactivated by heating to 100°C for 1 min; nonviability was then verified by plating onto Trypticase soy agar plates (Becton Dickinson & Co. Microbiology Systems, Sparks, Md.). Adult New Zealand White (NZW) rabbits (Covance, Denver, Pa.) were used for all studies, and all procedures were in accordance with the \textit{Guide for the Care and Use of Laboratory Animals} (14). Rabbits deprived of food for 16 h were challenged with salmonellae using a method adapted from Cray et al. (7). Animals were anesthetized with an intramuscular injection of ketamine and acepromazine (70 and 0.4 mg per kg of body weight, respectively) and then intravenously administered 50 mg of cimetidine (National Logistics Services, Owings Mills, Md.) per kg. Animals were then intubated using a pediatric feeding tube, and two doses of 5\% sodium bicarbonate were orally administered at 15-min intervals. The second dose of sodium bicarbonate was immediately followed by oral administration of 15 ml of bacterial culture at a concentration of 10^{11}, 10^{9}, 10^{7}, 10^{5}, or 10^{3} CFU per animal. The control animals were challenged with 10^{11} CFU of heat-killed salmonellae or with LB broth alone. To slow intestinal peristalsis, all animals were given an intraperitoneal injection of 2.0 ml of paregoric (2 mg/5 ml; National Logistics Services). Rabbits were examined for loose stool, diarrhea, anorexia, and weight loss. Rectal swabs were collected on a triweekly basis and cultured on Hektoen enteric agar (HEA) following 18 h of preenrichment in lactose broth.
A dose-response relationship was seen between time of challenge and time of animal death. All animals challenged with either $10^{11}$ or $10^9$ CFU of DT-9 developed symptoms which progressed from loose stool containing mucus by day 3 postinfection (p.i.) to watery diarrhea containing frank blood by day 5 p.i. All rabbits challenged with $10^{11}$ CFU died by day 5. Initial deaths of animals challenged with $10^9$ CFU were seen at day 3 p.i., with all rabbits succumbing to infection by day 7 p.i. Rectal swabs from the majority of animals in all challenge groups were positive for salmonellae (Table 1), and necropsy revealed fluid accumulation in the cecum and small intestine. One-half of all rabbits challenged with $10^7$ CFU of serotype Typhimurium developed watery diarrhea containing mucus and blood by day 5 p.i., and deaths were seen at day 10 p.i. (Fig. 1). Animal deaths in the $10^7$-CFU challenge group occurred after all rabbits challenged with $10^{11}$ and $10^9$ CFU had died, supporting the dose-response relationship between challenge and time of death. Twenty-five percent of animals challenged with $10^7$ CFU of DT-9 developed severe watery diarrhea containing mucus and blood. At the height of their illness, animals lost from 16 to 30% of their initial body weights, a significant loss compared with the results from the controls (Fig. 2). However, these animals began to recover from the infection on day 14 p.i., as evidenced by weight gain and increased food consumption. By day 23 p.i., the animals were symptom free and within 90% of their prechallenge weights (Fig. 2). Rectal swabs from these animals were salmonella negative by day 15 p.i. (Table 1). For approximately 7 days, the remaining 25% of the animals challenged with $10^7$ CFU exhibited occasional loose stools mixed with formed stools. These animals had a slight weight drop of $\leq 10\%$ of initial body weight between days 3 and 5 p.i., but weight loss was not significantly different from that of control animals during this time period (Fig. 2). Animals challenged with $10^5$ CFU exhibited no symptomatology, but salmonellae were recovered from the stools of these animals for up to 7 days p.i., indicating a viable bacterial challenge and some intestinal colonization. Rabbits challenged with $10^3$ CFU shed salmonellae in their feces for only 3 days p.i., indicating challenge with viable bacteria but no colonization.

Using pentobarbital (100 mg/kg), three representative rabbits challenged with $10^7$ CFU of serotype Typhimurium and three challenged with heat-killed salmonellae were euthanized after the onset of diarrhea in the challenge group (approximately 7 days p.i.). To assess bacterial colonization, a 1.0-ml sample of cecal contents and tissues of known weight from the

**FIG. 1.** Survival rates of adult NZW rabbits orally challenged with DT-9. Results were obtained from three separate trials with 4 rabbits per challenge or control group for a total of 12 animals per treatment and from one trial with 4 animals challenged with $10^5$ CFU and 4 heat-killed controls. All rabbits challenged with $10^{11}$ or $10^9$ CFU of DT-9 died from infection by day 7 p.i. A dose of $10^7$ CFU represented the 50% pathogenic endpoint for this isolate. All control rabbits and those challenged with $10^7$ and $10^5$ CFU survived challenge with DT-9.
upper and lower intestines, spleen, and liver were aseptically removed. Tissue samples were homogenized in phosphate-buffered saline, the homogenates and cecal contents were serially diluted 10-fold in phosphate-buffered saline, and 100 μl of each dilution was plated onto HEA plates and incubated at 37°C overnight. No viable bacteria were recovered from the tissues harvested from animals challenged with heat-killed serotype Typhimurium. However, viable *Salmonella* organisms were recovered from the cecal contents (1.2 × 10⁷ ± 1.5 × 10⁷), upper intestines (2.4 × 10⁵ ± 3.4 × 10⁵), and lower intestines (6.0 × 10⁵ ± 1.7 × 10⁵) of the rabbits challenged with 10⁷ CFU of DT-9. *Salmonella* was also recovered from the livers (6.4 × 10⁴ ± 1.0 × 10⁴) and spleens (9.8 × 10⁴ ± 8.7 × 10⁴) of the challenged animals, and blood cultures were salmonella positive. These results show that bacteremia and invasion of deep tissue can occur in this model.

These data show that, when this model is used, NZW rabbits develop a diarrheal syndrome comparable to that seen in human salmonella gastroenteritis. Animals responded in a dose-dependent manner, with a challenge of 10⁷ CFU representing the 50% pathogenic endpoint. These results also suggest that >10⁵ CFU is needed to establish diarrheal disease in rabbits. Animals challenged with heat-killed salmonellae showed no signs of clinical illness, indicating that viable *Salmonella* is required for development of diarrheal disease in this model and that symptoms are not the results of a preformed toxin(s) or lipopolysaccharide. Several rabbits also developed infection of the deep tissues and septicemia, sequelae associated with salmonella infection. Control animals that were fed culture media also remained symptom free, showing that growth media alone do not cause diarrhea in rabbits. To confirm that this model can be used with serotypes other than serotype Typhimurium, we completed a smaller study using an Enteritidis serotype isolated from a food-borne outbreak. The dose-response curve and symptomatology for this isolate were identical to those seen with the DT-9 study.

We thank Colleen Carroll for critical reading and editing of the manuscript.
