Received 8 April 2003/Returned for modification 8 May 2003/Accepted 15 August 2003

Paracoccidioidomycosis (PCM) is a systemic granulomatous mycosis whose agent is Paracoccidioides brasiliensis. In the culture supernatant, the fungus expresses glycoproteins of from 13 to 148 kDa. A cell surface glycoprotein of 43 kDa is the major antigenic component of P. brasiliensis. Another expressed glycoprotein, gp70, is recognized by 96% of sera from PCM patients and is able to induce lymphoproliferation. Since, little is known about this glycoprotein, we produced monoclonal antibodies (MAbs) against gp70 to isolate the molecule from total fungus extracts and to investigate its possible role in the pathogenesis of PCM. Using these MAbs, it was observed by confocal microscopy that gp70 is located mainly in the intracellular compartment of the fungus, although it was also detected in the culture supernatant. Based on observations showing that gp43 has a down-regulatory effect on mouse peritoneal macrophages, we tested the effects of gp70 on their phagocytic ability. Purified gp70 was able to inhibit the activity of macrophages through the mannose receptors and also through the Fc receptors; the latter effect was not observed with gp43. gp70 inhibits NO and H2O2 liberation by peritoneal macrophages in vitro, as does gp43. Results obtained with gp43 led us to hypothesize that gp70 could act as an escape mechanism for fungal establishment in primary infections. To corroborate this hypothesis, we analyzed the effect of passive immunization of mice during infection with P. brasiliensis using anti-gp70 MAbs. This treatment almost completely abolished granuloma formation in the lungs, suggesting that the protein facilitates fungal establishment and progression of lesions in primary infection.
cerative responses when tested with lymphocytes from PCM patients (3). gp70 was also detected, along with gp43, in the urine of patients exhibiting the acute form of PCM (44). However, despite its likely importance, this fungal component of *P. brasiliensis* has not yet been purified and carefully studied.

The pathophysiology of PCM is far from completely understood. Nevertheless, it is well established that macrophages constitute one of the primary mechanisms that arrest microbial invasion. It has been demonstrated that activated macrophages may have a central role in host resistance to systemic mycoses, such as coccidiodiomycosis (1, 2), histoplasmosis (53), blastomycosis (10), and PCM (7, 9). Microscopic studies showed that *P. brasiliensis* is able to multiply intracellularly in peritoneal and pulmonary resident macrophages, indicating that they are not fungicidal for ingested fungi (8). In contrast, lymphokine-activated macrophages were found to be fungicidal for ingested *P. brasiliensis* (7). Identification of the fungal surface molecules that mediate the interaction with macrophage receptors is certainly important for a understanding of the host-invader interplay. However, the interaction between *P. brasiliensis* components and macrophages is not yet fully understood.

Cell-mediated immunity is generally acknowledged to provide important host defense against most fungal infections. The role of antibody-mediated immunity in host resistance is less certain (17), despite considerable evidence that administration of specific monovalent antibodies (MAbs) can modify the course of infection in mice by certain pathogenic fungi, such as Cryptococcus neoformans and Candida albicans (18, 27, 29, 46).

In the present study, MAbs were produced against gp70 in order to isolate the molecule from total fungus extracts and to investigate its influence on the phagocytic abilities of mouse peritoneal macrophages. The effect of passive immunization of mice before infection with *P. brasiliensis* using the generated anti-gp70 MAbs was also analyzed. Treatment of mice by simultaneous injection of two MAbs directed to gp70 epitopes almost abolished lung infection. As this molecule also down regulates mouse peritoneal macrophage functions in vitro, we propose here that MAbs, by blocking the inhibitory effect of gp70 on phagocytes and probably on other immune effector cells, may facilitate the clearance of the fungi from lung tissues, thus aborting infection.

**MATERIALS AND METHODS**

**Fungal strains.** *P. brasiliensis* strains SS and 113 were maintained by frequent passages in mice before infection with *P. brasiliensis* (7). Identification of the fungal surface components and macrophages is not yet fully understood.

**Preparation of fungal antigens.** Yeast forms were grown at 35°C and subcultured every 5 days. All experiments described below were performed with both fungal strains, except the assay in vivo, in which a highly virulent isolate (Ph18) was used. To ensure the maintenance of its virulence, this isolate was used only after three passages in mice by intraperitoneal inoculation.

**Preparation of fungal antigens.** Yeast forms of *P. brasiliensis* were grown on Sabouraud glucose agar at 35°C for 3 days and transferred to 50 ml of TOM medium prepared in our laboratory with 6.1 g of yeast extract, 16.1 g of dextrose, 15 g of casein peptone, 0.31 g of K2HPO4, 0.12 g of MgSO4·7 H2O, 0.006 g of MnSO4·H2O, 0.006 g of NaCl, and 0.006 g of FeSO4 for 1,000 ml of distilled H2O at 37°C on a rotating shaker as previously described (41). This preinoculum was cultivated for 3 days and transferred into Fernbach flasks containing 500 ml of the same medium. After 10 days of incubation at 37°C, the cells were killed by the addition of 0.2 g of thimerosal per liter; the suspension was filtered through filter paper, and the resulting filtered material represented the crude exoantigen.

**Animals.** Male and female BALB/c mice, 6 to 10 weeks old, provided by the animal facilities of the Federal University of São Paulo, São Paulo, Brazil, were used throughout this study.

**SDS-PAGE and immunoblot analysis.** Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) was performed on vertical slab gels of 10% acrylamide according to the method of Laemml (32) and always under reducing conditions. Glycoproteins were stained with Coomassie brilliant blue, silver nitrate, or Periodic acid-Schiff. Immunoblotting was performed as described elsewhere (48).

**Immunization protocols.** In the first schedule of immunization, mice were intraperitoneally injected every 2 weeks for 4 months with macerated polyacrylamide gel containing 70-kDa glycoprotein (gp70). In a second schedule, mice were subcutaneously immunized every 2 weeks with 50 μg of gp70 (purified through MAbs obtained in the first fashion) in phosphate-buffered saline (PBS) with complete Freund’s adjuvant for the first injection and incomplete Freund’s adjuvant for the subsequent injections. Injections were always made in four different sites in the axillary and inguinal regions in a final volume of 100 μl per site. Before each immunization, the mice were bled through the ocular plexus, and the serum was separated by centrifugation and stored at −20°C. Final immunization was done intravenously 2 days before cell fusion.

**Fusion protocols.** Cells of the murine myeloma line sp2 were fused with spleen cells from immunized mice according to the method of Lopes and Alves (34). For the first fusion, hybridomas were distributed in 48-well plates (Costar Corp., Cambridge, Mass.), and 10 days postfusion, the colonies were screened by immunoblotting, as described below. For the second fusion, hybridomas were distributed in 96-well plates (Costar), and the screening was done by enzyme immunoblotting as described elsewhere (42). After cell cloning, purifying dilution and expanding of the positive clones, large amounts of antibodies were obtained from the ascites fluid injected in BALB/c mice injected with Pristane (Sigma) before the inoculation of hybridoma cells.

**Antibody screening by immunoblotting.** Exoantigens were fractionated by SDS-PAGE with 10% acrylamide under reducing conditions. The proteins were then transferred by electrophoresis to nitrocellulose membranes. Fragments of nitrocellulose membranes containing gp70 were cut in small pieces and distributed in 48-well plates (Costar). After free sites were blocked with PBS containing 5% skim milk, 200 μl of supernatants from the hybridomas cultures was added to each well. After 1 h of incubation at room temperature, the wells were washed five times for 5 min each time with PBS containing 0.1% Tween 20 (Sigma) and treated with affinity-purified peroxidase-conjugated goat anti-mouse immunoglobulin (Ig) (Bio-Rad) for 1 h at room temperature. The wells were washed five times with PBS containing 0.1% Tween 20. The presence of reactive IgG was tested by the addition of 4-chloro-nitro-tol in 50 mM Tris buffer, pH 6.8, and H2O2 and terminated with distilled water.

**gp70 purification.** Exoantigen of *P. brasiliensis* strains SS and 113, prepared separately as described above, was used as the antigen source. Purification of gp70 was performed by affinity chromatography in a Sepharose CNbr column coupled with MAbs (CA7/CSF11) from now on called CSF11) directed to gp70 epitopes. This MAb was purified from both culture supernatants and ascites fluids by affinity chromatography in a protein G column. Ig was purified using a mouse antibody immobilizing kit (Gibco) according to the manufacturer’s instructions.

The gp70 concentration was determined by the Bradford method (4). All steps of gp70 purification were monitored by SDS-PAGE.

**ELISA.** Enzyme-linked immunosorbent assays (ELISAs) were carried out as described elsewhere (42). Briefly, plates were coated with 1 μg of purified gp70/ml in PBS, 50 μl per well, for 1 h at 37°C. Blocking of free sites on plastic was done with 5% PBS– milk for 1 h at 37°C. Anti-gp70 MAbs were added in various concentrations (5, 10, 20, and 40 μg/ml in PBS; 50 μl per well). After 1 h, the plates were incubated with anti-mouse IgG (horseradish peroxidase conjugated in PBS; 50 μl per well) (Bio-Rad). Between the incubation steps, the wells were washed three times with PBS– 0.1% Tween 20– 0.7% gelatin. After incubation for 1 h at 37°C and washing of the wells, substrate solution (1 mg of O-phenylenediamine in 5 ml of 0.1 M citrate-phosphate buffer [pH 5.0] plus 10 μl of 30% H2O2) was added to each well, and the reaction was interrupted by the addition of 50 μl of 2 N H2SO4 per well. Optical densities were read in a Multiskan MCC/340 II EIA reader at 492 nm.

**Recognition of gp70 by MAbs.** To investigate whether gp70 was recognized only when purified or also in living fungi, an ELISA was devised. Live fungi were bound to the plastic substrate through binding by human polyclonal anti-*P. brasiliensis* serum. On the side, purified gp70 was directly bound to the surface. After washing and quenching of the plastic surface as described above, the reaction was developed with mouse anti-gp70 MAbs.

**Inhibition assay.** In order to ascertain the nature of gp70 epitopes to which MAbs were directed, whether carbohydrate or protein, polyvinyl plates were coated with purified gp70 and incubated with 20 μg of anti-gp70 MAbs/ml after being previously incubated for 1 h under constant agitation with 25, 50, and 100 mM solutions of mannose, galactose, glucose, and α-methyl-d-mannopyranoside.
After this incubation period, the concentrations of IgG in these preparations were determined as previously described.

IEF. Isoelectric focusing (IEF) was performed with the Pharmacia LKB (Uppsala, Sweden) PhastSystem apparatus. One microgram of affinity-purified gp70 from \textit{P. brasiliensis} SS and/or 113 was submitted to IEF analysis using PhastGel IEF (Pharmacia) in a pH range of 3 to 9 according to the manufacturer’s instructions. Standard markers for isoelectric point (pI) determination of proteins in the same pH range (Pharmacia) were used. gp70 was developed by silver staining (PhastGel Silver kit; Pharmacia).

Confocal microscopy. Yeast forms of \textit{P. brasiliensis} from 5-day-old cultures grown in yeast extract-peptone-dextrose broth medium were fixed for 60 min with 0.5 ml of 3.5% formaldehyde in PBS and washed as before. The pellets were resuspended in 0.1 ml of PBS, and 10 \(\mu\)l of each cell suspension was applied to the microwells of fluorescence slides. The cells were incubated with 50 mM ammonium chloride for 60 min, followed by 1 h of incubation with 0.1% Triton X-100 diluted in PBS–0.2% gelatin. Anti-gp70 MAbs were added at a concentration of 50 \(\mu\)g/ml diluted in PBS–0.2% gelatin and incubated for 2 h. Finally, fluorescein-conjugated secondary antibody was added together with DAPI (4',6'-diamidino-2-phenylindole)-stained nuclei for 60 min of incubation. All steps were followed by constant washing with PBS. The slides were mounted with 5% buffered glycerol to minimize bleaching.

Images of DAPI-stained cells were observed in a Bio-Rad 1024 UV confocal system attached to a Zeiss Axiovert 100 microscope, using a 40\(\times\) numerical-aperture 1.2 plan-apochromatic differential interference contrast water immersion objective. All images were collected by Kalman averaging at least every eight frames (512 by 512 pixels), using an aperture (pinhole) of 2 mm.

Peritoneal macrophages. Peritoneal macrophages were used as representatives of nonspecific response. Any differences from alveolar macrophages could not be checked due to the very small amount of gp70 available. Cells were collected from the abdominal cavities of BALB/c mice by repeated washing with 5 ml of fresh RPMI 1640. Peritoneal macrophages from all of the mice were pelleted by centrifugation at 390 \(\times\) g rpm for 4 min and then pooled. The peritoneal macrophages were resuspended in R10 medium and distributed in wells of tissue culture plates. The cultures were incubated at 37\(^\circ\)C in 5% CO\(_2\) for 1 h. Nonadherent cells were removed by aspiration, and RPMI 1640 with 10\% (vol/vol) heat-inactivated fetal bovine serum (R10) was added to the adherent monolayers.

For the phagocytic assays, \(5 \times 10^5\) peritoneal macrophages were resuspended in 0.5 ml of R10 and dispensed in 24-well tissue culture plates (Costar) containing round glass coverslips in the bottom. Adherent monolayers were rinsed with 0.5 ml of R10. The macrophages were maintained in culture for 72 h.

To determine NO and H\(_2\)O\(_2\) liberation by these cultures, \(2 \times 10^5\) peritoneal

\end{figure}
cells in 0.15 ml of R10 were distributed in wells of a 96-well tissue culture plate. Adherent cell monolayers were rinsed with 0.05 ml of R10, and the macrophages were maintained in culture for 48 h.

**Phagocytic assays.** Phagocytic assays were done with macrophages maintained in culture for 72 h. gp70 dissolved in R10 medium at different concentrations (25, 50, and 100 μg/ml) was added to macrophage cultures. After 5 min of incubation with gp70, zymosan particles (10 mg/ml) were added to the cultures. After 60 min, the coverslips were vigorously washed with PBS and fixed in 2% glutaraldehyde. These preparations were analyzed under phase-contrast microscopy. The same protocol was used to evaluate the influence of gp70 on the uptake of sheep red blood cells previously opsonized with subagglutinating doses of rabbit IgG anti-sheep red blood cells at 37°C for 1 h. The preparations were stained by Hema 3 (24) and analyzed by optical microscopy. The viability of the macrophages was always checked by trypan blue exclusion.

An average of 200 phagocytic cells were counted in the control group to represent 100%.

**NO determination.** Peritoneal macrophage cultures as described above were incubated with different concentrations of gp70 (0.125, 0.25, 0.5, and 1 μg/ml), and after 48 h, the concentration of NO2 in the culture supernatant was measured with the Griess reagent (1% sulfanilamide, 0.1% naphthylethylenediamine dihydrochloride, 25% H3PO4). All assays were done in triplicate. The concentration of gp70 used was the result of previous experiments in our laboratory.

**H2O2 determination.** Peritoneal-macrophage cultures as described above were stimulated with 10 ng of lipopolysaccharide (LPS)/ml and 10 IU of gamma interferon (IFN-γ) or unstimulated and were treated with 1 μg of gp70/ml or left untreated. After 2 days, a phenol red solution (PBS, 5 mM dextrose, 50 μg of horseradish type II, 0.28 mM phenol red) was added to the cells for 1 h at 37°C, and the reaction was stopped by the addition of 10 μl of 1 N NaOH solution. A standard curve for the determination of the H2O2 concentration in the experimental tests was constructed using H2O2 solution varying from 0.5 to 4 nmol. Absorbance was measured at 620 nm in a microtiter plate reader (MR 4000; Dynatech Chantilly).

**Passive immunization.** Five groups of eight male BALB/c mice each (8 to 10 weeks old) were used. All groups were infected intratracheally with the Pb18 strain of *P. brasiliensis*, as previously described (16), and received different treatments by the intravenous route. The first group received 100 μl of PBS, the second group received 100 μg of an irrelevant MAb (anti-CEA [carcinoembryonic antigen]), the third group received 100 μg of MAb 1B7D6 (from now on called B7D6), the fourth group received 100 μg of MAb C5F11, and the fifth group received 100 μg each of MAbs B7D6 and C5F11. To ensure the maintenance of the concentrations of antibodies in serum throughout the infection, the MAbs were administered 3 days before and every 3 days after infection over a period of 45 days.

**CFU determination.** Mice of each experimental group were sacrificed after 45 days of infection, and the numbers of viable microorganisms in the lungs, liver, and spleen were determined by the CFU method as previously described (3). The results of CFU studies were confirmed by two identical protocols.

**Histopathology.** Fragments of lungs, livers, and spleens from mice of the different experimental groups were fixed in 10% formalin for 24 h and embedded in paraffin. Tissue sections (5 μm thick) were obtained and stained with hematoxylin and cosin.

**Statistics.** Statistical comparisons were made by analysis of variance and the Tukey-Kramer test. All values were reported as the mean ± standard error of the mean.
RESULTS

MAb generation and antigen purification. After cloning and selection, five stable MAbIs that specifically recognized gp70 from *P. brasiliensis* were obtained. MAbIs 1A7C5F5F11 and 2B8A6D2 were of the IgG1 isotype, and MAbIs 1E6B1F4, 1E6B8F3, and 2E7A2C4 were of the IgM isotype (all κ light chains). The IgG1 MAb C5F11 was coupled to Sepharose 4B CNbr and used to isolate the antigen by affinity chromatography. gp70 was purified from exoantigens produced by strains SS and 113 (Fig. 1A and B).

In order to investigate whether gp70 expressed different isoforms, an IEF assay was carried out. The results showed that the isolated protein presented a single isoform with a pI of 3.4. Conversely, gp43, used here for comparison, has several isoforms with pIIs ranging from 5.85 to 6.8 (Fig. 1C).

In another set of fusion experiments, one MAb directed to epitopes of gp70, B7D6, was obtained and characterized as IgG1. The binding of MAbIs to gp70 was evaluated by EIA (Fig. 2). gp70 was also recognized by the MAbIs in live fungi adhering to the plastic surface by human polyclonal anti-*P. brasiliensis* serum (data not shown).

Inhibition assays. To analyze whether anti-gp70 MAbIs bind the 70-kDa glycoprotein through epitopes composed of peptides or carbohydrates, inhibition assays were performed. The results showed that MAb C5F11 binds to a peptide epitope, whereas MAb B7D6 is partially inhibited by carbohydrates (Fig. 3).

Confocal microscopy. Using two anti-gp70 antibodies, B7D6 and C5F11, confocal microscopy was employed to determine the localization of gp70 in the fungus in the yeast phase. It was observed that gp70 was present in the intracellular milieu (Fig. 4).

Inhibition of phagocytosis in vitro. To investigate whether gp70 influences phagocytosis through the mannose receptor, zymosan particles (10 mg/ml) were added to peritoneal-macrophage cultures previously supplied with different concentrations of gp70 (25, 50, and 100 μg/ml). The results showed that purified gp70 inhibited phagocytosis of zymosan particles in a dose-dependent manner (Fig. 5). The maximal inhibition of phagocytic activity was obtained with 100 μg of gp70/ml.
As shown in Fig. 6, gp70 also influences phagocytosis through the Fc receptor. At a concentration of 25 μg of gp70/ml, a marked inhibition in the uptake of opsonized sheep red blood cells was observed.

**NO and H₂O₂ release.** The influence of gp70 on NO and H₂O₂ release by cultured macrophages was investigated. The results showed that gp70 inhibited basal NO production by nonactivated peritoneal macrophages, with an initial concentration of 0.125 μg/ml (Fig. 7). Similarly, gp70 also inhibited H₂O₂ production by peritoneal macrophages activated or not with LPS and IFN-γ (Fig. 8).

**Passive immunization.** To evaluate whether administration of IgG1 anti-gp70 MAb could alter the course of PCM, BALB/c mice were infected intratracheally with *P. brasiliensis* and intravenously treated with anti-gp70 MAb. After 45 days of infection, the average time for the establishment of infection by yeast cells, the number of CFU in the lungs of animals treated with MAb B7D6 was similar to that in controls. Reduction in the number of CFU in mice treated with MAb CSF11 was observed, but a significant decrease in the number of CFU was obtained only with the group that received concomitant administration of both MAbs CSF11 and B7D6 (Fig. 9). Histopathology of lungs from infected and treated animals confirmed the CFU results. The lungs of control animals presented an inflamed parenchyma with a large cellular infiltrate, mainly of the mononuclear type, and well-organized granulomas with great numbers of viable yeast cells, most of them within the cytoplasm of phagocytic cells. Similar results were observed in the lungs of mice treated with an irrelevant MAb. The lungs of animals that received MAb B7D6 presented a minor reduction in parenchyma inflammation and granulomas. Mice treated with CSF11 showed well-preserved parenchymas with large peribronchial cellular infiltrates and did not present yeast cells or granuloma formation. The lung parenchymas of the animals treated with both the antibodies B7D6 and CSF11 were similar to those of the CSF11 group, but moderate peribronchial cellular infiltrate was not regularly observed (Fig. 10).

The histopathology and CFU of livers and spleens of all treated mice, including control animals, did not show the presence of fungus (data not shown).

**DISCUSSION**

The agent of PCM, *P. brasiliensis*, like many other eukaryotic parasites, expresses several antigenic molecules that may be recognized by antibodies produced by human patients or raised in immunized laboratory animals. The chemical natures of these components and their participation in the pathophysiology of the fungus are poorly known, since very few molecules have been isolated in pure form and subsequently characterized.

gp43 is the main purified diagnostic specific antigen when used in liquid phase serologic tests (6), since it is recognized by 100% of PCM patients’ sera (49, 50). MAbs against gp43 have been used in a capture immunoassay for the specific detection of antibodies in patients with PCM (11). gp43 has been shown to bind laminin, a protein component of the extracellular matrix of mammalian tissues, and laminin-coated yeasts have increased ability to invade and destroy tissues. Based on these data, gp43 on the surfaces of yeast cells has been proposed to act as a laminin receptor (52). A T-cell epitope in gp43 has been mapped to a 15-residue sequence, and immunization with the corresponding oligopeptide elicited a protective response against virulent *P. brasiliensis* (47). Furthermore, DNA-based vaccination using the gp43 gene led to protective immunity against *P. brasiliensis* in BALB/c mice (40). It has recently been demonstrated in our laboratory that gp43 down regulates mouse peritoneal-macrophage functions, such as phagocytosis, via mannose receptors, liberation of free radicals, and the microbicidal activity of these cells for *P. brasiliensis* (21).
by ELISA, it seems to be a valuable marker of active PCM in immunoblotting reactions. gp70 and gp43 induce lymphoproliferative responses when tested with lymphocytes from PCM patients (3), and gp70 is also detected, along with gp43, in the urine of patients (44). Otherwise, little is known about the 70-kDa glycoprotein, and the purpose of the present work was to attempt to better understand its role in PCM.

We have produced and characterized six MAbs against gp70, three of which had their isotypes established as IgG1(κ) and the others as IgM(κ). We noticed that the IgG1 MAb C5F11 reacted with peptide sequences of gp70, while the IgG1 MAb B7D6 could be inhibited by carbohydrates. Immunoblotting assays revealed that all MAbs reacted with gp70 and in EIAs, and only one of the MAbs (2B8A6D2) did not recognize gp70. This antibody probably binds to different configurations of the glycoprotein, although some variations in sensitivity may depend on the assay used.

gp70 was successfully purified from exoantigen, as seen by silver-stained SDS-PAGE or periodic acid-Schiff staining. We also observed that gp70 has only one isof orm, with an acid pI of 3.4, thus differing from gp43, which has several isoforms with basic pIs ranging from 6.85 to 5.8. Confocal microscopy analysis showed that gp70 is predominantly located in the intracellular compartment of the fungus, although a small amount was also detected in the culture supernatant. The same epitope of gp70 could be detected in both live fungi and purified protein, showing that despite being mainly a cytoplasmic protein, it is also expressed on the fungus surface (data not shown). Use of purified antigens led to an increased titer of antibodies, as detected by ELISA in hybridoma culture supernatants and mouse ascites fluid, suggesting that their use in serologic tests could increase the sensitivity for antibody detection, and thus, that gp70 could represent a possible target for immunodiagnostic studies.

FIG. 10. Histopathology of lung sections of P. brasiliensis-infected BALB/c mice 45 days after infection. (A) Control mice show well-organized granulomas (arrows) and a high number of yeast cells (magnification, ×100). (B) Granulomatous lesion from control group showing intact fungi and typical macrophages and epithelial cells (magnification, ×400). (C) Mice treated with MAb B7D6 show smaller, well-organized granulomas (arrows) with a high number of yeast cells (magnification, ×100). (D and E) Mice treated with MAb C5F11 (D) and mice treated concomitantly with both MAbs C5F11 and B7D6 (E) show absence of both yeast cells and granulomas (magnification, ×400). (F) Nongranulomatous lung from both MAb-treated mice, predominantly composed of a mononuclear infiltrate in which fungi are not seen (magnification, ×100).
These MAbs could also be useful for the detection of the epitopes involved in the interaction of the antigen with cells and components of the biological system being studied. The main targets of this investigation were macrophages, the first line of the host’s defense. The mononuclear phagocytic system constitutes an important effector mechanism in the natural and adaptive immune responses against several pathogens. It has been suggested that macrophages play a fundamental role in resistance to *P. brasiliensis* (31). This function depends upon their state of activation, which leads to microbicidal activity.

Previous studies have demonstrated that murine peritoneal cells activated by IFN-γ exert a fungicidal effect on both the yeast and conidial forms of *P. brasiliensis* (5, 14, 15). Based on these findings, in this study we tested the effect of gp70 on the phagocytic ability of mouse peritoneal macrophages. It was demonstrated that purified gp70, at from 25 to 100 μg/ml, was able to inhibit phagocytosis of zymosan particles in a dose-dependent fashion. This inhibition probably occurred because the predominant components of gp70 are polysaccharides, which bind to mannose receptors on the surfaces of macrophages, thus blocking the binding of zymosan particles and consequently their phagocytosis. gp43 has a similar effect on the inhibition of phagocytosis of zymosan particles by macrophages (21).

We also observed that gp70 inhibited phagocytosis of opsonized sheep red blood cells, although not in a dose-dependent manner. This result supports the notion that gp70 inhibits the activity of phagocytic macrophages not only through the mannose receptor but also through the Fc receptor, in which it differs from gp43, which does not have the latter effect (21).

Macrophages activated by IFN-γ, tumor necrosis factor alpha, or LPS produce two kinds of reactive products that characterize their cytotoxic activity: reactive oxygen intermediates and reactive nitrogen intermediates. Nitric oxide, one of the most important reactive nitrogen intermediates, is responsible for the cytotoxic effect exerted on a variety of microorganisms, including parasites such as *Schistosoma mansoni* (30), and several fungi, such as *C. neoformans* (22) and *H. capsulatum* (33, 37). Hydrogen peroxide is one of the most important reactive oxygen intermediates. Since gp70 inhibits phagocytosis, we analyzed the effect of this glycoprotein in the liberation of these products, and we noticed that, like gp43, the 70-kDa glycoprotein decreases the release of both NO and H₂O₂ by macrophages (21).

The use of vaccines that stimulate humoral or cellular immunity can theoretically elicit protection against fungal pathogens. There is conclusive evidence that humoral immunity can modify the course of infection of some pathogenic fungi. *C. neoformans* has a polysaccharide capsule which is essential for its virulence, and MAbs reactive against it can protect against experimental cryptococcosis (19, 23, 36). It was also demonstrated that an IgG3 MAb was not protective in various mouse models of cryptococcal infection, while an IgG1 MAb significantly prolonged survival (39, 54). However, when the nonprotective IgG3 MAB was switched to IgG1, an increase of antibody protective efficacy occurred.

For another fungus, *C. albicans*, antibodies to cell wall polysaccharides were protective against experimental disseminated candidiasis (25, 28). Also, it has been shown that the efficiency of antibody protection depends on epitope specificity (26). These studies demonstrate a complex relationship among the efficacy of antibody protection, epitope specificity, and isotype.

In this paper, we analyzed the effect of passive immunization of mice infected with *P. brasiliensis* using the generated anti-gp70 IgG1 MAbs. A significant reduction in the number of CFU in the lungs was observed when MAbs CSF11 and B7D6 were administered concomitantly, thus confirming results seen with CFU. Histopathology of lung sections showed improvement of the infection with a reduction in the number of fungus particles and granulomas within the organ.

Despite gp43 being considered the main antigenic component of *P. brasiliensis*, the effect of passive immunization using the anti-gp43 IgG2a MAbs did not produce similar results (unpublished data).

The nature of the mechanisms which underlie the abortion of lung infection in mice treated with MAbs directed to gp70 epitopes is a complex issue. Nevertheless, two non-mutually exclusive hypotheses could be put forward. First, antibodies could be reacting with gp70 on the fungus surface, thus facilitating phagocytosis and killing of the fungal particles. Second, by neutralizing the macrophage-down-regulatory effect of the protein, macrophages could be free to eliminate the parasite. In both proposals, these mechanisms would work in the beginning of the infection, since we are far from understanding the mechanisms which determine the progression of infection in PCM and other types of infectious diseases. Negative results obtained with MAbs directed to gp43 could be due to the existing isomers of the molecule, impairment in the neutralization of its effects, or opsonization of the fungal particles.

Antibodies have been considered the hallmarks of a more severe disease in PCM, while protection has always been attributed to cellular immune response. Here, it is shown for the first time that antibodies by themselves can abrogate establishment and development of the disease. Although these mechanisms have not yet been discovered, it is possible to suppose that vaccination with gp70 or its active fragments could provide an armamentarium, not yet available, to control the incidence of PCM in areas of endemicity.
