\textit{Acanthamoeba castellanii} mannose-binding protein (MBP) mediates adhesion of the amoebae to corneal epithelial cells, a key first step in the pathogenesis of \textit{Acanthamoeba} keratitis (AK), a devastating corneal infection. In the present study, we demonstrate that oral immunization with recombinant MBP ameliorates AK in a hamster animal model and that this protection is associated with the presence of elevated levels of anti-MBP immunoglobulin A in the tear fluid of the immunized animals.

\textit{Acanthamoeba castellanii} keratitis (AK) is a rare but painful and devastating infection of the cornea that is difficult to diagnose and treat (2, 4, 8, 11, 13, 16). We have recently shown that \textit{Acanthamoeba} express a mannose-binding protein (MBP) that mediates the adhesion of the amoebae to corneal epithelial cells (3, 5, 6, 18) and that anti-MBP immunoglobulin A (IgA) antibodies are present in the human tear fluid of healthy individuals (G. N. Alberti, M. Garate, Z. Cao, D. Zoukrhi, M. Goldstein, K. H. Wu, and N. Panjwani, Abstr. ARVO Annu. Meet., abstr. 4969, 2004). Because MBP mediates adhesion of the \textit{Acanthamoeba} to host cells, the presence of anti-MBP-specific IgA in tear fluid may provide protection against the infection by blocking the adhesion of amoebae to the corneal surface. In this respect, it has been reported that the levels of anti-\textit{Acanthamoeba} IgA antibodies are reduced in tears (1) and sera (17) of patients with AK. The goal of the present study was to test the hypothesis that the mucosal immune system resulting in the production of anti-MBP IgA may be instrumental in providing protection against AK.

Chinese hamsters (\textit{Cricetulus griseus}, 4 to 6 weeks old; Cyto-\-gen Research and Development, Inc., West Roxbury, MA) were orally immunized with a highly purified preparation of recombinant MBP (rMBP) (5) according to the regimen depicted in Fig. 1. All animals were handled in accordance with recommendations of the NIH Guide for the Care and Use of Laboratory Animals. Prior to immunization, corneas of all animals were examined under an operating microscope to exclude animals with any preexisting corneal disease (12). Two trials, MBP trials 1 and 2, were conducted. In trial 1, a group of 6 animals was immunized by oral administration of 100 \(\mu\)g of rMBP plus 10 \(\mu\)g of neutralized cholera toxin (CT) in 100 \(\mu\)l of phosphate-buffered saline. The animals were boosted by administration of three consecutive weekly doses of the same amount of antigen and CT. A control group of 6 animals was sham immunized with vehicle (phosphate-buffered saline) alone. We have previously shown that the control animals immunized with CT alone as well as control antigens (e.g., lysozyme), are not protected against AK in this model (9). In MBP trial 2, the same immunization regimen was used except that the animals were immunized with 200 \(\mu\)g of rMBP instead of the 100 \(\mu\)g rMBP used in the MBP trial 1. Seven days after the fourth oral immunization, the infection was induced by placing \textit{A. castellanii} (ATCC 30868, axenically cultured, >95% trophozoites)-laden contact lenses on scarified corneas of one eye of each animal as described previously (7, 9). After 4 days, corneas were examined under a dissecting microscope to assess the severity of infection based on the presence of corneal infiltration, neovascularization, and corneal ulceration. On a scale of 0 to 4, 0 represented no infection and scores of 1 to 4 indicated that 10\%, >10 to <25\%, 25 to <50\% and >50\% of the cornea, respectively, was affected by the disease. A score of 1.0 on any of the criteria represented infection. Clinical severity scores were analyzed by the Mann-Whitney test. In this model, the AK has a self-limiting course of 3 weeks (7, 9).

As expected (7, 9), control animals immunized with vehicle alone developed severe keratitis (mean severity score on postinfection day 5, 1.85 ± 0.5 \([n = 6, \text{trial 1}]\); 1.83 ± 0.5 \([n = 5, \text{trial 2}]\) that was cleared by day 22 (Fig. 2A). In MBP trial 1, all 6 animals were protected (Fig. 2A). In MBP trial 2, 4/6 animals were protected (data not shown) (severity scores on

postinfection day 5, 0 [2 animals], 0.8, and 1.0; severity scores on postinfection day 7, 0 [2 animals], 0.12, and 0.63), and two were not protected (severity scores on postinfection day 5, 2.0 and 2.25; severity scores on postinfection day 7, 1.25 and 1.62). On average, oral immunization with MBP in trials 1 and 2 reduced the severity of infection by 86% and 57%, respectively, and reduced the duration of the disease by 12 and 5 days, respectively. Overall, significant protection was achieved in both trials, but the lower dose (100 μg) appeared to be more efficacious. Additional studies are needed to optimize the

FIG. 2. Immunization of Chinese hamsters with rMBP ameliorates amoebic keratitis. (A) Hamsters were orally immunized with rMBP (100 μg) and were challenged with *A. castellanii*-infected contact lenses. The severity of infection was recorded beginning on postinfection day 5. The severity score was significantly lower for the rMBP-immunized group (solid circles) than for the sham-immunized control group (open circles). Data are presented as means ± standard errors (n = 6 for each group). (B) Representative photographs of eyes on postinfection day 12. *, P < 0.05 compared to control group.

FIG. 3. Tears of rMBP-immunized animals contain elevated levels of anti-MBP IgA antibodies. Tears were collected during the immunization period on days 0, 7, 14, and 21 and were analyzed individually for the presence of anti-MBP IgA by ELISA. The assay was performed using various dilutions of tears with protein concentrations from 9.4 to 75 μg/ml. Results of tears collected on day 14 (A) and day 21 (B) are shown. Data are presented as means ± standard errors (n = 6 for each group). *, P < 0.05 compared to control group. No difference in the antibody level was detected between the immunized and control groups in the tear samples collected on day 0 and day 7 (not shown). OD, optical density.
dose and immunization regimen for achieving maximum protection. In an effort to understand the mechanism by which the oral immunization provides protection against AK, we measured the anti-MBP IgA in tears of immunized animals using an enzyme-linked immunosorbent assay (ELISA) procedure described previously (7, 9). There was no significant difference in the anti-MBP IgA levels between the control and the immunized groups in the tear samples collected on day 0 and day 7 (not shown). In contrast, anti-MBP IgA levels were significantly higher in the immunized animals than in the control group in the tear samples collected on day 14 (Fig. 3A) as well as day 21 (Fig. 3B). It is noteworthy that 2/6 animals that were not protected in MBP trial 2 had antibody titers that were similar to those of the animals which were fully protected (average optical density values of ELISAs on day 21 at a protein concentration of 75 μg/ml: control animals, 0.016 ± 0.003 [n = 6]; immunized animals [protected], 0.047 ± 0.002 [4/6]; immunized animals [not protected], 0.045 [2/6]). This may suggest that an immune response against a specific region of MBP may be required to provide protection and that the animals which were not protected may have elicited an immune response against a distinct region(s) of MBP compared to the animals which were protected. This reasoning stems from the observations of Petri et al. (14, 15) and Lotter et al. (10) demonstrating that, in a gerbil model of Entamoeba infection, immune response specifically against the C-terminal domain encompassing the carbohydrate recognition domain (CRD) of Entamoeba histolytica galactose-specific lectin is protective, whereas the immune response against the N-terminal domain of the lectin is not protective and, in fact, exacerbates the disease.

We have recently cloned and sequenced Acanthamoeba MBP (5) and have shown that the architecture of the lectin is characteristic of a cell surface receptor consisting of a large extracellular domain, a single-pass transmembrane domain, and a short cytoplasmic domain which is located at the C terminus. At present, the exact location of the CRD in the amoeba MBP is not known. The study described herein lays the foundation for future studies to pinpoint the exact location of the CRD and to characterize individual domains of the amoeba MBP with respect to their roles in host-parasite interactions.
