Chlamydia trachomatis is an obligate intracellular bacterium that infects the oculogenital mucosae. *C. trachomatis* infection of the eye causes trachoma, the leading cause of preventable blindness. Infections of the genital mucosae are a leading cause of sexually transmitted diseases. A vaccine to prevent chlamydial infection is needed but has proven difficult to produce by using conventional vaccination approaches. Potent immunity to vaginal rechallenge in a murine model of chlamydial genital infection has been achieved only by infection or by immunization with dendritic cells (DC) pulsed ex vivo with whole inactivated organisms. Immunity generated by infection or ex vivo antigen-pulsed DC correlates with a chlamydia-specific interleukin 12 (IL-12)-dependent CD4⁺ Th1 immune response. Because of the potent antichlamydial immunizing properties of DC, we hypothesized that DC could be a powerful vehicle for the delivery of individual chlamydial antigens that are thought to be targets for more conventional vaccine approaches. Here, we investigated the recombinant chlamydial major outer membrane protein (rMOMP) as a target antigen. The results demonstrate that DC pulsed with rMOMP secrete IL-12 and stimulate infection-sensitized CD4⁺ T cells to proliferate and secrete gamma interferon. These immunological properties implied that rMOMP-pulsed DC would be potent inducers of MOMP-specific CD4⁺ Th1 immunity in vivo; however, we observed the opposite result. DC pulsed ex vivo with rMOMP and adoptively transferred to naive mice generated a Th2 rather than a Th1 anti-MOMP immune response, and immunized mice were not protected following infectious challenge. We conclude from these studies that the immunological properties of ex vivo pulsed DC are not necessarily predictive of the immune response generated in vivo following adoptive transfer. These findings suggest that the nature of the antigen used to pulse DC ex vivo influences the Th1-Th2 balance of the immune response in vivo.

Chlamydiae are successful and complex obligate intracellular parasites with a unique biphasic life cycle comprised of an infectious elementary body (EB) and a noninfectious reticulate body (22, 26, 43). *Chlamydia trachomatis* is an epithelium-tropic parasite of humans, and infections of the oculogenital mucosae are the cause of trachoma, the leading cause of preventable blindness in developing countries, and a major cause of sexually transmitted diseases (25, 47). Antibiotic treatment effectively eradicates infection. However, asymptomatic infections are common (>50%) and, when left untreated, can progress to chronic disease, an impasse that questions whether effective intervention can be managed by anti-infective agents alone. It is likely that the most effective form of intervention for diseases caused by *C. trachomatis* will be a vaccine (6, 19, 28, 44, 45). However, there has been little progress in the development of an efficacious vaccine because of a lack of understanding of adaptive protective immunity against *C. trachomatis* infection of the genital tract. Only recently has an understanding of adaptive immunity to infection become apparent as a result of independent studies from a number of laboratories using a murine model of female genital tract infection (1, 42). Collectively, these independent investigations

have resulted in highly corroborative findings providing compelling evidence that protective immunity against *C. trachomatis* infection of the genital mucosae is mediated by a cooperative interaction of CD4⁺ Th1 T cells and B cells (8, 13, 18, 20, 21, 24, 32, 36, 46, 48). Although the exact mechanism(s) that mediates the eradication of chlamydiae from the genital mucosae has yet to be precisely defined, it is evident that gamma interferon (IFN- γ) is an important effector cytokine, particularly in the clearance of infections caused by human strains (11, 12). Despite this knowledge, there has been only minimal progress in the development of a conventional vaccine that is effective in preventing chlamydial genital infection.

Presently, the only proven means of eliciting potent protective immunity against *C. trachomatis* infection in murine genital mucosae is infection itself or adoptive immunization with dendritic cells (DC) pulsed ex vivo with killed chlamydial EBs (37). Interestingly, immunization with antigen-pulsed DC elicits levels of protective immunity equivalent to those generated by infection. The potent adjuvant properties of DC, particularly their ability to generate Th1 immune responses (29) and their propensity to home to follicular sites of systemic and mucosal lymphatic tissues (30), likely account for their superior antichlamydial immunizing properties. It is unrealistic to propose a therapeutic role for ex vivo antigen-pulsed DC as a practical antichlamydial vaccine for use in humans. However, the exceptional antichlamydial immunizing properties of DC-based cellular vaccines make them preeminent vehicles for

screening candidate chlamydial vaccine antigens that have potential for more conventional vaccine development.

The *C. trachomatis* major outer membrane protein (MOMP) (4) is regarded as the most promising vaccine candidate (3, 5, 44, 49). It is surface accessible and highly immunogenic, eliciting both neutralizing antibodies and T-cell responses (33, 35). Moreover, the MOMP has been implicated as a chlamydial cytoadhesin (39, 40) that mediates attachment by binding to host glycoaminoglycan receptors (38). Attempts to vaccinate mice against chlamydial infection of the genital tract by using recombinant MOMP (rMOMP) (41), synthetic peptides corresponding to MOMP T- and B-cell epitopes (33, 34), or DNA-based immunogens (23) have met with only marginal success. The inability to generate potent protective immunity by using these MOMP-based immunogens likely is multifactorial, but it is possible that an optimum protective immune response against the MOMP requires the use of an immunogen that more closely mimics the native conformation of the protein (31). It has been shown that, following purification, a recombinant maltose binding protein (MBP)-rMOMP fusion protein exists as ca. 30-nm colloidal particles that effectively compete with viable chlamydial EBs for attachment to HeLa 229 cells (38); this finding implies that rMOMP possesses sufficient native structural characteristics to mediate its cytoadhesin function and hence may represent a more native antigenic structure.

We hypothesized that the rMOMP particles might represent a rational antigen for pulsing DC and for targeting a potent anti-MOMP Th1 response in vivo. In this report, we test this hypothesis. The results showed that although DC pulsed ex vivo with rMOMP secreted interleukin 12 (IL-12) and presented processed MOMP antigen to infection-sensitized CD4⁺ T cells that secreted IFN- γ , they elicited a nonprotective Th2 rather than a protective Th1 immune response following adoptive transfer. These results imply that the in vitro immunological profiling of antigen-pulsed DC cannot be used to consistently predict their in vivo immunizing characteristics, suggesting that a more thorough understanding of DC maturation following adoptive transfer is required to optimally use their potent immunizing properties as cellular vaccines.

MATERIALS AND METHODS

Chlamydiae. The *C. trachomatis* mouse pneumonia strain (MoPn) was grown in HeLa 229 cells and infectious EBs were purified by density gradient centrifugation as previously described (3).

Mice. Female C57BL/10 (*H-2^b*) mice between 8 and 12 weeks of age were purchased from Jackson Laboratory (Bar Harbor, Maine). Animals were housed in accordance with the Association for Assessment and Accreditation of Laboratory Animal Care in filter-top cages under standard environmental conditions and provided food and water ad libitum.

DC. Bone marrow-derived DC were generated from female C57BL/10 mice (6 to 12 weeks old) by using a modified version of the method of Inaba et al. (9). Briefly, femurs were removed from mice, and bone marrow cells were flushed from femurs and cultured in IMDM-10 (GIBCO BRL) supplemented with 10% fetal bovine serum, 10 μ g of gentamicin sulfate/ml, 10 ng of granulocyte-macrophage colony-stimulating factor (GM-CSF)/ml, and 10³ U of IL-4 (PharMingen)/ml at 2 \times 10⁶ cells/ml in 100-mm tissue culture dishes. On day 3 of culturing, the nonadherent cells were removed and fresh medium containing GM-CSF and IL-4 was added. On day 5 of culturing, DC were isolated by transferring the nonadherent and loosely adherent cells to new culture plates (leaving behind the adherent macrophages), incubating the plates at 37°C for at least 2 h, and then repeating the procedure to remove any contaminating macrophages. The DC were further enriched (>95% purity) by density gradient centrifugation with

14.5% metrizamide solution (Sigma) in culture medium. DC purity was characterized by cell size, dendritic morphology was characterized by phase-contrast microscopy, and viability was assessed by trypan blue exclusion. DC populations were characterized for purity by fluorescence-activated cell sorting analysis after staining with anti-*I-A^b*, anti-CD86, anti-CD40, and anti-CD11b antibodies. DC cultures were also analyzed by fluorescence-activated cell sorting following staining with anti-Gr1, anti-CD3, anti-CD19, and anti-pan-NK monoclonal antibodies (MAbs) for enumerating contaminating granulocytes, T cells, B cells, and NK cells, respectively. In general, CD11b-positive DC showed high levels of MHC class II, CD86, and CD40 expression. Isolated DC contained less than 5% contamination with T, B, or NK cells (results not shown).

Pulsing DC with rMOMP. Day 5 DC were panned twice and purified by density gradient centrifugation. DC (5 \times 10⁵ DC in 1 ml of IMDM-10) were incubated in the presence 1.2 mg of rMOMP for 1 h at 37°C with gentle mixing every 15 min. The biological and physical properties of the *C. trachomatis* MoPn rMOMP particles were previously described (38). The purified fusion protein exists as ca. 30-nm colloidal spheres that specifically bind to and efficiently compete with infectious EBs for cultured HeLa 299 cells. Purified MBP was used as a control antigen. The cells were centrifuged, washed twice with IMDM-10, and plated on IMDM-10-GM-CSF (10 ng/ml) overnight. On the following day, the cells were fixed in methanol, stained with murine MAb 33B (specific for the MoPn MOMP), and then stained with a secondary fluorescein isothiocyanate-conjugated goat anti-mouse immunoglobulin G (IgG) antibody. DC were viewed by fluorescent-antibody staining and confocal microscopy for internalization of rMOMP.

T-cell proliferation assay. Spleens were harvested from immune mice (animals that had resolved primary genital infections), and a single-cell suspension in phosphate-buffered balanced salt solution-5% fetal bovine serum was made. Magnetic CD4⁺ (L3T4) and CD8⁺ (Ly-2) microbeads (Miltenyi Biotec) were used for positive selection of CD4⁺ T cells and CD8⁺ T cells, respectively (37). Immune T cells were then plated in round-bottom 96-well plates at 3 \times 10⁵ cells/well. DC that had been pulsed overnight with rMOMP were harvested, and 4 \times 10³ DC were incubated with 1.2 \times 10⁴ T cells in 100 μ l of medium. Forty-eight hours later, 1 μ Ci of ³H-thymidine (78.4 Ci/mmol; LIFESCIENCE-NEN) was added to each well. Radioactive cultures were incubated overnight, and counts per minute were measured by using a TopCount NXT microplate scintillation counter (Packard Instrument Company, Meriden, Conn.) to assess thymidine uptake or incorporation.

Antibody and cytokine ELISAs. Chlamydia-specific serum antibodies (IgG1 and IgG2a) and IgA in mouse vaginal secretions were assayed by an enzyme-linked immunosorbent assay (ELISA) with formalin-fixed MoPn EB and alkaline phosphatase-conjugated goat anti-mouse IgG antibodies (Southern Biotechnology Associates, Birmingham, Ala.) as described previously (18, 37). Cytokines were measured by an ELISA with the corresponding specific capture and detection antibodies, and cytokine quantities were calculated by using standard curves constructed with recombinant murine cytokines as described by the manufacturer (PharMingen).

Adoptive immunization with antigen-pulsed DC. Female C57BL/10 mice (6 to 12 weeks old) were used as bone marrow donors. DC were propagated and enriched as described above. Mice (four to eight per treatment group) were adoptively immunized by intravenous (retro-orbital) injection with 4 \times 10⁶ to 7 \times 10⁶ DC pulsed with either MBP, rMOMP, or heat-killed (HK) EBs suspended in Hanks balanced salt solution (37). A booster immunization was administered 14 days after the initial immunization, and mice were bled and vaginal wash specimens were collected 5 to 8 days following the booster immunization. One week following the booster immunization, mice were injected subcutaneously with 2.5 mg of medroxyprogesterone acetate (Depo-Provera; Pharmacia and Upjohn Company, Kalamazoo, Mich.) per mouse to synchronize the estrous cycle prior to the infectious challenge. One week following the medroxyprogesterone acetate injection, mice were challenged intravaginally with 20 μ l of MoPn (150 infection-forming units [IFU] are equivalent to 10 50% infective doses). Protection was assessed by quantifying the chlamydial burden isolated from cervicovaginal swab samples taken at 7 days postchallenge.

RESULTS

Phagocytosis of rMOMP by DC. We first investigated whether DC efficiently ingested rMOMP particles. Bone marrow-derived DC were pulsed with a range of concentrations (0 to 60 μ g of protein) of rMOMP, washed, and reseeded on glass coverslips. At different times after pulsing, the medium was removed

FIG. 1. Endocytosis of rMOMP by DC. (A) Phase-contrast photomicrograph of rMOMP-pulsed DC. (B) Fluorescent-antibody staining of rMOMP-pulsed DC. DC (5×10^5 cells) were pulsed with 1.2 μg of rMOMP in 1 ml of medium for 1 h at 37°C, washed, and incubated overnight at 37°C with 10 ng of GM-CSF/ml. DC were fixed in methanol and stained with an anti-mouse MAb specific for *C. trachomatis* MoPn MOMP (MAb 33B). A goat anti-mouse antibody conjugated to fluorescein isothiocyanate was used for secondary staining. Arrows indicate the punctate staining of antigen along the perimeter of the DC surface. No staining was observed when unpulsed DC were stained with MAb 33B or when rMOMP-pulsed DC were stained with a negative control MAb (EVI-H1) specific for chlamydial LPS (data not shown).

and the cells were washed, fixed in methanol, and examined for MOMP antigen by fluorescent-antibody staining. DC exhibiting the highest frequency and intensity of staining for rMOMP were those pulsed with 1.2 μg of rMOMP/ml at a DC density of 10^5 cells/ml for 1 h (Fig. 1). Under these conditions, the majority (>95%) of cultured DC stained positive for MOMP antigen 24 h after pulsing. Fluorescence was consistently observed as a particulate staining pattern localized at the cell periphery. Confocal microscopy of pulsed DC confirmed the intracellular location of immunoreactive material (results not shown).

DC pulsed with rMOMP secrete IL-12. It was previously shown that DC pulsed ex vivo with HK EBs secrete IL-12, a potent Th1-polarizing cytokine, and that following adoptive transfer to naive mice, these DC generated a potent chlamydia-specific protective CD4^+ Th1 immune response. It was therefore of interest to compare the cytokine profiles found in the supernatants of DC pulsed with rMOMP and DC pulsed with HK EBs. The culture supernatants of DC pulsed with HK EBs or rMOMP for 48 h were assayed for IL-12 (p40), IL-10, IL-6, and IL-4. We found that DC pulsed with either HK EBs

FIG. 2. DC pulsed ex vivo with rMOMP secrete IL-12. DC were cultured alone or following pulsing with HK EBs or rMOMP. After 48 h of incubation, culture supernatants were collected and assayed by an ELISA for cytokines IL-12, IL-10, IL-6, and IL-4. A representative from two independent experiments is shown.

FIG. 3. Infection-sensitized CD4⁺ T cells proliferate in response to DC pulsed with rMOMP. CD4⁺ and CD8⁺ T cells were collected from mice that had resolved a *C. trachomatis* (MoPn) genital infection. Infection-sensitized T cells were incubated for 48 h in the presence of T cells alone, DC alone, T cells plus DC, T cells plus DC and rMOMP, or T cells plus MBP. T-cell proliferation was measured by pulsing cells with ³H-thymidine overnight, and cell-associated radioactivity was determined by using a TopCount NXT microplate scintillation counter. Experiments were performed in triplicate, and counts per minute are expressed as the mean and standard deviation. The asterisk denotes a *P* value of 0.01 (Student's two-tailed *t* test) for a comparison of CD4⁺ T cells pulsed with rMOMP fusion protein or with MBP alone.

or rMOMP secreted IL-12 (Fig. 2). Neither DC population secreted IL-10 or IL-4, and only DC pulsed with HK EBs secreted IL-6.

Immune CD4⁺ T cells proliferate in response to DC pulsed with rMOMP. We next investigated whether DC pulsed with rMOMP presented antigen to either CD4⁺ or CD8⁺ T cells isolated from the spleens of mice that had resolved a primary infection of the genital tract and were immune to rechallenge. We found that CD4⁺ but not CD8⁺ T cells proliferated in response to DC pulsed with rMOMP (Fig. 3). A vigorous proliferative response occurred following incubation of CD4⁺ T cells with rMOMP-pulsed DC. DC pulsed with the MBP fusion partner alone also stimulated immune CD4⁺ T cells to proliferate. Importantly, however, immune CD4⁺ T cells showed a significantly greater response to DC pulsed with the rMOMP fusion protein (*P* = 0.01) than to DC pulsed with MBP alone, demonstrating that rMOMP was specifically recognized by CD4⁺ T cells in the context of chlamydial genital tract infection.

Immune CD4⁺ T cells secrete IFN- γ in response to DC pulsed with rMOMP. To determine the type of MOMP-specific CD4⁺ T cells (Th1 or Th2) that were being activated in response to infection, we assayed IL-4, IL-10, and IFN- γ in the culture supernatants of DC alone, DC pulsed with MBP, and DC pulsed with rMOMP by an ELISA (Fig. 4). No detectable cytokines were found in culture supernatants of unpulsed DC propagated with immune CD4⁺ T cells. IFN- γ was detected in

high concentrations (900 pg/ml) relative to IL-10 and IL-4 (280 and 0 pg/ml, respectively) in culture supernatants obtained from CD4⁺ T cells incubated with DC pulsed with rMOMP. Both cytokines were detected, but at much lower levels, in supernatants of CD4⁺ T cells cultured with MBP-pulsed DC. Moreover, the cytokine profile was reversed compared to that observed for rMOMP-pulsed DC, with IL-10 (270 pg/ml) being present at higher concentrations than IFN- γ (53 pg/ml). These findings indicate that the reactivity found in the immune CD4⁺ T-cell population against the MBP fusion partner was mediated by a CD4⁺ Th2 rather than a Th1 subset of cells.

The following conclusions can be drawn from the above results. (i) DC cultured in vitro efficiently ingest rMOMP particles; (ii) pulsed DC secrete IL-12 following uptake of rMOMP particles; (iii) pulsed DC present processed MOMP antigen to CD4⁺ T cells; and (iv) the responding CD4⁺ T cells secrete IFN- γ , indicative of a Th1 phenotype. Thus, genital infection generates an MOMP-specific CD4⁺ Th1 immune response. Therefore, we hypothesized that it should be possible to immunize mice with rMOMP-pulsed DC to generate an MOMP-specific CD4⁺ Th1 immune response and then to challenge mice to ascertain if this immunity was protective.

Immunization of mice with rMOMP-pulsed DC generates a CD4⁺ Th2 immune response. Naive mice were immunized with DC alone, DC pulsed with HK EBs, or DC pulsed with rMOMP. The anti-MOMP humoral and CD4⁺ T-cell immune

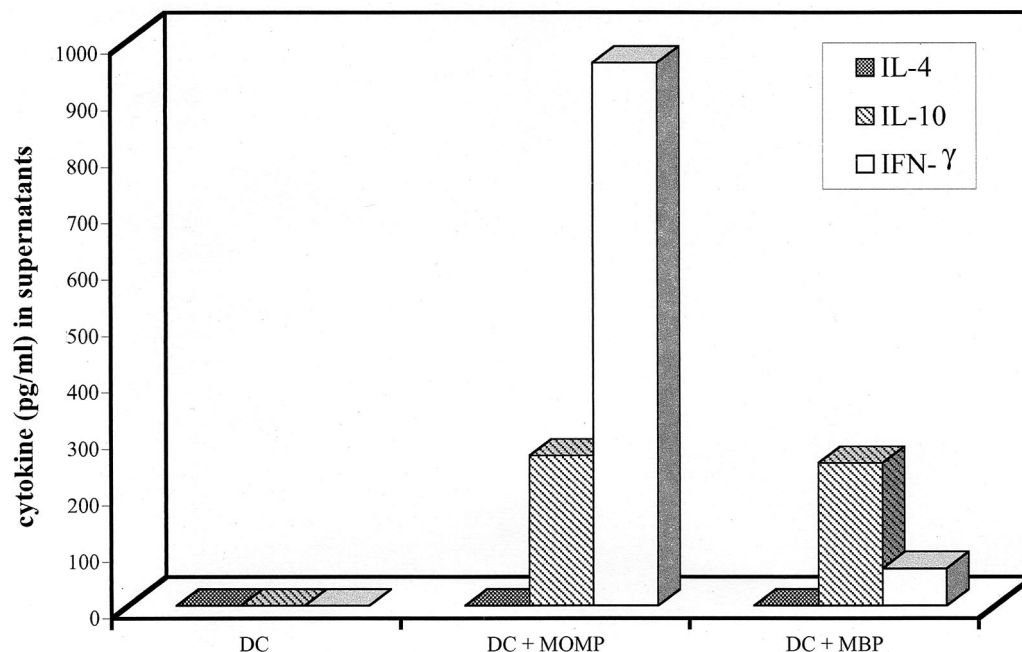

FIG. 4. Infection-sensitized CD4⁺ T cells secrete IFN- γ in response to DC pulsed with rMOMP. Infection-sensitized CD4⁺ T cells were incubated in the presence of unpulsed DC (DC), DC pulsed with rMOMP, and DC pulsed with MBP for 48 h, and supernatants were collected. Levels of IL-4, IL-10, and IFN- γ in supernatants were measured by an ELISA. A representative from two independent experiments is shown.

responses were tested following immunization. Serum anti-chlamydial IgG1 and IgG2a antibodies were assayed by an ELISA with formalin-fixed MoPn EBs as the antigen. CD4⁺ T-cell immunity was assessed by determining the concentrations of IL-4, IL-10, and IFN- γ in the supernatants of splenocytes cultured with formalin-treated MoPn EB antigen. Infected immune mice and mice immunized with DC pulsed with HK EBs produced a mixed IgG1 and IgG2a antichlamydial response (Fig. 5). In contrast, mice immunized with DC pulsed with rMOMP showed a predominant IgG1 response. Vaginal wash specimens obtained from mice immunized with rMOMP-pulsed DC were negative for chlamydia-specific IgG and IgA (results not shown). No antichlamydial antibodies were detected in the sera of mice immunized with MBP-pulsed DC. These findings showed that rMOMP immunization generated an antibody response capable of reacting with intact protein on the chlamydial cell surface, strongly implying that rMOMP retained at least some structural characteristics in common with the native protein. Conversely, the predominant IgG1 antibody response indicated that the anti-MOMP response was Th2 rather than Th1 biased.

To more directly test this hypothesis, CD4⁺ T cells isolated from rMOMP-immunized mice were assayed for antigen-specific production of IL-4, IL-10, and IFN- γ (Fig. 6). CD4⁺ T cells from infected immune mice or mice immunized with DC pulsed with HK EBs generated a Th1 cytokine profile characterized by elevated concentrations of IFN- γ , moderate levels of IL-10, and no detectable IL-4. In contrast, CD4⁺ T cells from mice immunized with rMOMP-pulsed DC produced no IFN- γ but did secrete moderate levels of both IL-4 and IL-10, a cytokine profile characteristic of a Th2 response.

Mice immunized with rMOMP-pulsed DC are not protected

against chlamydial challenge. We next challenged mice immunized with rMOMP-pulsed DC intravaginally to assess protective immunity. Naive mice, infected immune mice, and mice immunized with HK EB-pulsed DC were included as negative and positive controls. As previously shown, both infected immune mice and mice immunized with DC pulsed with HK EBs were significantly more resistant to intravaginal challenge than naive controls, with a reduction in the levels of recoverable organisms of 3.8 and 4.4 log₁₀ units, respectively (Fig. 7). On the other hand, mice immunized with rMOMP-pulsed DC were not protected, as shown by equivalent levels of shedding of infectious organisms in these mice and in intravaginally challenged immunologically naive mice. Thus, in contrast to infected immune mice or mice immunized with HK EB-pulsed DC, mice immunized with rMOMP-pulsed DC produced a CD4⁺ Th2 immune response that did not protect against chlamydial challenge of the genital tract.

DISCUSSION

We have proposed that because of their potent adjuvant properties and capability of immunizing against chlamydial genital tract mucosal colonization and infection (37), ex vivo antigen-pulsed DC will be useful as an antigen delivery system for screening the immunogenicity and protective efficacy of candidate chlamydial vaccine antigens. In the work described here, we investigated this hypothesis by using the chlamydial MOMP as a target antigen. Although there have been numerous attempts to immunize female mice by using rMOMP (41), MOMP peptides (34), or naked DNA encoding MOMP (23) incorporated in a number of adjuvants, these approaches have yielded either negative findings or only partial protective im-

FIG. 5. Mice immunized with rMOMP-pulsed DC produce a chlamydia-specific IgG1 antibody response. Sera were collected from mice that had resolved a *C. trachomatis* (MoPn) genital infection (infected), mice immunized with chlamydia-pulsed DC (DC + HK EB), mice immunized with rMOMP-pulsed DC, and mice immunized with MBP-pulsed DC. An ELISA was used to measure the levels of chlamydia-specific IgG1 and IgG2a antibodies. Mice previously infected with chlamydiae or immunized with chlamydia-pulsed DC generated high titers of IgG2a; however, mice immunized with rMOMP-pulsed DC produced only IgG1. Mice immunized with MBP-pulsed DC (control) did not produce chlamydia-specific antibodies. A representative from two independent experiments is shown. A 1:256 dilution of serum was used for all assays.

munity following intravaginal challenge. There are likely many possible explanations for the inability of MOMP-based vaccines to generate potent protective immunity of the genital mucosae. One possibility, suggested by Stephens (31) and Zhang et al. (49), is that in order to achieve optimum utility of MOMP as a vaccine, the protein must be delivered in a non-denatured native conformation to elicit a recall response to infection-specific T- and B-cell epitopes. Validation of native MOMP is not possible, because its crystal structure has yet to be determined; therefore, the native conformation can be implied only through indirect analysis, such as its interaction with antibodies that bind to conformationally dependent epitopes or maintenance of biological activity. Toward this end, it was previously shown that the rMOMP fusion protein forms colloidal particles of about 30 nm and that the rMOMP particles specifically bind to HeLa 229 cells and, most importantly; compete with the binding of infectious EBs (38). Based on these findings, we suggested that MOMP binding to its cognate host receptor was dependent on its native configuration. Therefore, because of the superior ability of ex vivo pulsed DC to generate a Th1 immune response and the evidence supporting MOMP as a promising vaccine candidate, it was logical to investigate whether rMOMP-pulsed DC could function in mediating an anti-MOMP Th1 response and, if so, whether this response would be protective.

We found that rMOMP was efficiently ingested by DC, a finding likely due to the colloidal nature of the recombinant

protein. Of further interest, however, was the observation that rMOMP-pulsed DC produced IL-12 and stimulated infection-sensitized CD4⁺ T cells to proliferate and secrete IFN- γ . These findings demonstrate that rMOMP-pulsed DC present antigen in the context of class II to CD4⁺ T cells generated in response to natural infection. Moreover, the secretion by rMOMP-pulsed DC of IL-12, a potent stimulator of Th1 immunity, suggests that rMOMP-pulsed DC had the potential to generate an anti-MOMP CD4⁺ Th1 immune response in vivo. Furthermore, our finding that antibodies induced by rMOMP-pulsed DC reacted with the surface of intact EBs provides additional evidence that rMOMP retained certain native structural characteristics. In all, these results were very encouraging, leading us to believe that rMOMP-pulsed DC would be efficient inducers of CD4⁺ Th1 immunity. In fact, we observed the opposite result. Mice adoptively immunized with rMOMP-pulsed DC generated a CD4⁺ Th2 response, as shown by the predominant serum IgG1 antibody response and the secretion of IL-4 and IL-10 but not IFN- γ by cultured CD4⁺ T cells. Not unexpectedly and consistent with the immune response elicited by rMOMP-pulsed DC, immunized mice were not protected following chlamydial genital challenge. This finding was unlike that observed following adoptive immunization with HK EB-pulsed DC, which elicited potent protective CD4⁺ Th1 immunity.

What are some of the possible explanations for these contradictory findings? Culturing murine bone marrow cells with

FIG. 6. CD4⁺ T cells isolated from mice immunized with rMOMP-pulsed DC secrete IL-4 and IL-10. CD4⁺ T cells were harvested from mice that had resolved a *C. trachomatis* (MoPn) genital infection (infected), mice immunized with chlamydia-pulsed DC (DC + HK EB), and mice immunized with rMOMP-pulsed DC. T cells were incubated in the presence of antigen-presenting cells pulsed with whole chlamydial EB antigen (EB), and supernatants were collected 72 h later. An ELISA was used to measure the levels of IL-4, IL-10, and IFN- γ in culture supernatants. A representative from two individual experiments is shown.

GM-CSF and IL-4 gives rise to immature DC. Immature DC differentiate into subclasses of CD8 α^+ or CD8 α^- , which direct the development of distinct Th-cell populations in vivo (16, 17). Antigen-pulsed CD8 α^+ cells induce a Th1 response,

whereas CD8 α^- cells induce a Th2 response. It is therefore possible that pulsing of DC ex vivo with inactivated intact chlamydiae and rMOMP differentially drives DC populations to the CD8 α^+ and CD8 α^- phenotypes, respectively. Chlamy-

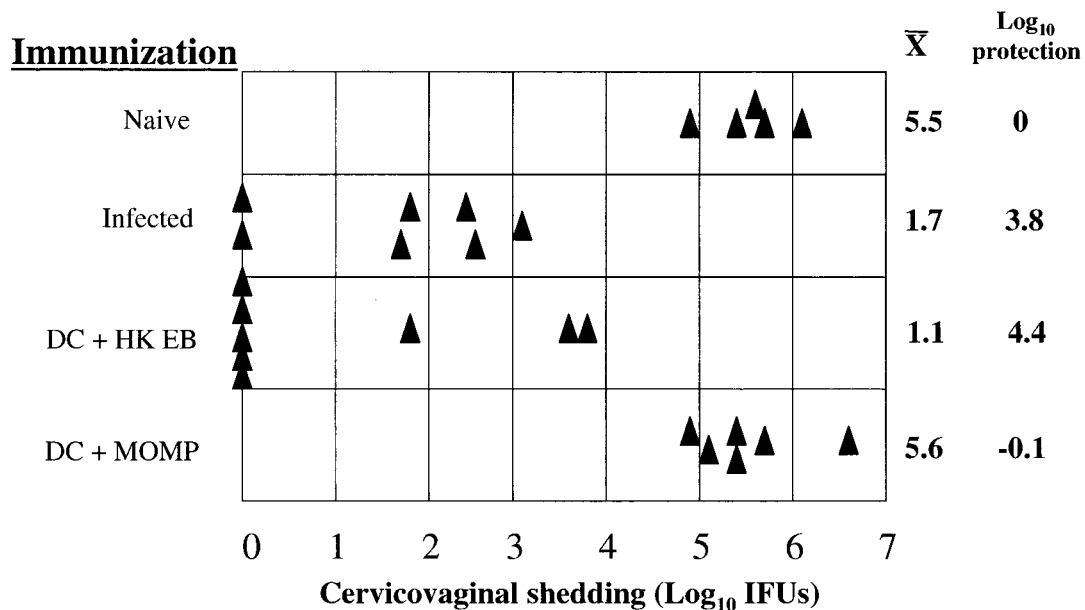

FIG. 7. Mice immunized with rMOMP-pulsed DC are not protected following chlamydial challenge. Mice were given no immunization (naive), 150 IFU intravaginally (infected), 7×10^6 DC pulsed with whole inactivated chlamydial EBs (DC + HK EB), and 7×10^6 DC pulsed with rMOMP (DC + MOMP) and then challenged intravaginally with 150 IFU of chlamydiae. Recoverable IFU were determined from cervicovaginal swab samples 7 days following challenge. Triangles represent individual mice. Log₁₀ mean organisms shed from the cervicovaginal region and log₁₀ protection are shown to the right of the graph. Mice immunized with unpulsed DC, HK EB alone (no DC vehicle), and MBP-pulsed DC did not show protection (data not shown).

iae are similar to gram-negative bacteria and possess lipopolysaccharide (LPS) (2). Chlamydial LPS differs structurally from gram-negative bacterial LPS molecules, and these structural alterations are known to reduce its endotoxin activities (15). Nevertheless, highly purified chlamydial LPS and chlamydial heat shock protein 60 have been shown to bind the CD14 LPS receptor and activate CD14 signal transduction pathways (10, 14). Therefore, it is possible that chlamydial LPS or heat shock protein 60 or other activating EB moieties influence DC maturation toward the CD8 α^+ phenotype, which then induces a protective antichlamydial Th1 immune response. In contrast, rMOMP that lacks similar inflammatory molecules may preferentially drive the development of the CD8 α^- phenotype, with the subsequent generation of a nonprotective Th2 immune response.

The potent in vivo immunizing properties of chlamydia-pulsed DC (27, 37) make them useful delivery vehicles for screening promising candidate chlamydial vaccine antigens. However, it is evident from the results reported here that further manipulation of DC populations to regulate their capacity to skew Th1-like immunological properties in vivo will be necessary to achieve an optimum outcome of vaccination. Future experiments with rMOMP-pulsed DC should focus on culture conditions that induce DC maturation toward the CD8 α^+ phenotype which, in theory, would generate an anti-MOMP Th1 immune response. Perhaps this goal can be accomplished by using MOMP-pulsed IL-10-deficient DC (F. O. Eko, W. Lubitz, and J. U. Igietseme, Abstr. 101st Gen. Meet. Am. Soc. Microbiol., p. 341, 2001) or by formulating MOMP vaccines to include CD8 α^+ -inducing molecules. It is also possible that more traditional vaccine strategies designed to target anti-MOMP Th1 immunity to mucosal surfaces 7; Eko et al., Abstr. 101st Gen. Meet. Am. Soc. Microbiol.) will yield effective vaccines against this most important pathogen; however, these approaches have not yielded the superior level of protective immunity at the genital mucosae that is conferred by antigen-pulsed DC.
